A Specific Transmembrane Domain of a Coronavirus E1 Glycoprotein Is Required for Its Retention in the Golgi Region

Carolyn E. Machamer and John K. Rose
Molecular Biology and Virology Laboratory, The Salk Institute for Biological Studies, San Diego, California 92138

Abstract. The E1 glycoprotein of the avian coronavirus infectious bronchitis virus contains a short, glycosylated amino-terminal domain, three membrane-spanning domains, and a long carboxy-terminal cytoplasmic domain. We show that E1 expressed from cDNA is targeted to the Golgi region, as it is in infected cells. E1 proteins with precise deletions of the first and second or the second and third membrane-spanning domains were glycosylated, thus suggesting that either the first or third transmembrane domain can function as an internal signal sequence. The mutant protein with only the first transmembrane domain accumulated intracellularly like the wild-type protein, but the mutant protein with only the third transmembrane domain was transported to the cell surface. This result suggests that information specifying accumulation in the Golgi region resides in the first transmembrane domain, and provides the first example of an intracellular membrane protein that is transported to the plasma membrane after deletion of a specific domain.

The intracellular transport and targeting of proteins from their site of synthesis to their correct destination is a process instrumental to maintenance of cellular integrity. Membrane-bound and secreted proteins are sorted from cytoplasmic proteins and those destined for the nucleus or mitochondria by virtue of a signal or leader sequence which directs insertion into the lumen of the endoplasmic reticulum (Walter et al., 1984). Plasma membrane and secreted proteins follow a similar pathway through the cell, from the rough endoplasmic reticulum through the Golgi complex en route to the plasma membrane (Sabatini et al., 1982). Other proteins in this exocytic pathway are retained at points along the way, such as cytochrome P-450 in the endoplasmic reticulum (Brands et al., 1985) and galactosyl transferase in the Golgi complex (Roth and Berger, 1982). Lysosomal enzymes are sorted to lysosomes after passage through the Golgi complex. Some lysosomal enzymes are sorted via a specific marker, a mannose-6-phosphate modification of asparagine-linked (N-linked) oligosaccharides of these enzymes, which is recognized by a receptor (Sly and Fischer, 1982).

The process of intracellular transport to the plasma membrane could be governed by positive sorting signals; i.e. proteins with these signals would be transported to the cell surface via a type of receptor-mediated process, like that involved in targeting of lysosomal enzymes. Alternatively, as recently suggested by Kelly (1985) and Rothman (1986), proteins that are destined for the plasma membrane or for constitutive secretion could move passively with the bulk flow of lipids, while proteins secreted in a regulated manner or those retained in intracellular membranes would possess signals which selectively retain them from moving with the bulk flow of membranes. A third model could invoke both positive signals that enhance the rate of incorporation of proteins into transport vesicles, and negative retention signals that ensure intracellular proteins to not be transported beyond a certain point.

Recombinant DNA technology that uses gene expression and site-directed mutagenesis offers a powerful approach to the study of intracellular transport and targeting. For example, using this approach, an involvement of cytoplasmic domains of proteins has been suggested in facilitating both exocytosis (Rose and Bergmann, 1983) and endocytosis (Lehrman et al., 1985; Roth et al., 1986), and in targeting of proteins to basolateral membranes of polarized epithelial cells (Mostov et al., 1986; Puddington et al., 1987). Although specific molecules interacting with these domains have not yet been identified, these results suggest that important interactions with cytoplasmic domains do occur.

Viruses provide simple and useful model systems for studying the signals involved in targeting of membrane proteins in cells. The coronaviruses provide an especially interesting model because they bud from intracellular membranes rather than from the plasma membrane. The best-studied...
members of the coronavirus group are mouse hepatitis virus (MHV) and avian infectious bronchitis virus (IBV). Both viruses specify two glycoproteins called E1 and E2 (reviewed by Sturman and Holmes, 1985). E2 forms the virion spike and can be detected in the plasma membrane as well as intracellular membranes of infected cells. In contrast, E1 accumulates intracellularly, and thus appears to play a critical role in intracellular budding of the virus. The viral nucleocapsid interacts with the MHV E1 protein, presumably the cytoplasmic tail, and virion budding occurs at the site of E1 accumulation in infected cells (Sturman et al., 1980; Dubois-Dalque et al., 1982; Tooze et al., 1984).

The sequences of cDNAs encoding El proteins from both MHV and IBV have been recently reported (Armstrong et al., 1984; Boursnell et al., 1984). These sequences predict polypeptides with a similar structure: a short, glycosylated amino-terminal domain, three hydrophobic domains believed to span the membrane three times, and a long cytoplasmic domain at the carboxy terminus. Studies that use protease treatment of intact virus (Sturman and Holmes, 1977; Cavanagh et al., 1986) or of E1 inserted into microsomal membranes (Rottier et al., 1984) support the model for the structure of E1. Since there is no cleaved amino-terminal signal sequence (Rottier et al., 1984), and the protein is inserted into microsomal membranes in a signal recognition particle-dependent manner (Rottier et al., 1985), it has been suggested that one or more of the putative membrane-spanning domains functions as an internal, uncleaved signal sequence.

We report here that the IBV E1 glycoprotein is retained in the Golgi region of the cell in the absence of the other viral proteins when expressed from cDNA. In an earlier study using gene expression and mutagenesis techniques, we determined that the cytoplasmic domain of the IBV E1 protein did not contain a signal that was capable of retaining the G protein of vesicular stomatitis virus (VSV) in intracellular membranes (Puddington et al., 1986). Thus, in the present study we chose to search for a retention signal in the amino-terminal half of the IBV E1 protein. We report that the first of the three membrane-spanning domains may constitute such a signal, and our results are discussed in terms of current models for protein transport to the plasma membrane.

Materials and Methods

Construction of an Expression Vector Encoding IBV E1

A cDNA clone encoding the El protein of the Beaudette strain (M42) of IBV was derived from viral genomic RNA and kindly provided by D. Stern (pIBV-5; Stern, 1983). A subclone containing the entire coding region was prepared (p57-6), and the nucleotide sequence was determined by the procedure of Maxam and Gilbert (1977). This sequence predicts a polypeptide with 225 amino acids, and differs at only two nucleotides from the sequence published by Boursnell et al. (1984) for the El protein of the Beaudette strain of IBV. These differences were a T instead of a C at nucleotide 167 and a C instead of a T at nucleotide 287, changing the codon for Pro 2 and for Thr 71 to that for Ser and Ile, respectively. A fragment that contains the entire coding sequence of IBV El, 773 bp, was excised from p57-6 with Hpa I and deoxynucleoside triphosphates to remove the 3' overhang. After ligation with Xho I linkers, the fragment was cloned into the unique Xho I site of M13 mp18.

Two synthetic oligonucleotides were used to precisely delete coding sequences such a signal, and our results are discussed in terms of current models for protein transport to the plasma membrane.

Oligonucleotide-directed Mutagenesis

Synthetic oligonucleotides were used to precisely delete coding sequences for putative membrane-spanning domains of El. The negative strand of the IBV El gene was cloned into the Bam HI site of M13 mp8 as described (Rose et al., 1984), and single-stranded phage DNA was purified for use as the template for mutagenesis. Synthetic oligonucleotides (3 mers) were designed to loop out specific regions of the coding sequence by hybridizing with 16 nucleotides on the 5' side of the loop and 17 nucleotides on the 3' side. The domain junctions were assigned on the basis of secondary structure and hydrophobicity predictions for IBV E1 (Boursnell et al., 1984; Rottier et al., 1986). The oligonucleotide used to generate the coding sequence for the mutant protein that lacked the second and third hydrophobic domains (Am2,3) was

5'-GTTAGGGATACGCAAGAAGCTTATGAGCGGTG-3'

and that for the mutant protein that lacked the first and second hydrophobic domains (Am1,2) was

5'-CCGCTTCTTTTAAAGAGGAGGAGCCGTGTCGCCGAC-3'.

They were synthesized and purified as previously described (Rose et al., 1984; Machamer et al., 1985). After hybridization of the oligonucleotide with the template DNA, primer extension was carried out with the Klown fragment of DNA polymerase I (Boehringer Mannheim Biochemicals, Indianapolis, IN) by the procedure previously described (Adams and Rose, 1985; Machamer et al., 1985). After transfection of competent Escherichia coli JM103 with the primer extension mixture, plaques containing the mutations were identified by differential hybridization with the 5'-[32P]P'-labeled oligonucleotide. DNA containing the mutation was excised and subcloned into the expression vector pClC19, and the mutation confirmed by DNA sequence analysis (Maxam and Gilbert, 1977). The mutant protein Am2,3 was created by fusion of the codon for Thr 42 to that for Arg 42 (deleting 156 nucleotides), and Am1,2 by fusion of the codon for Gln 20 to that for Gly 77 (deleting 168 nucleotides).

Cells and Virus

Both COS-1 and HeLa cells were maintained in Dulbecco-Vogt's modified Eagle's medium with 5% FCS. The IBV used in these experiments was adapted to growth in monkey cells by nine consecutive passages of egg-grown virus at a high multiplicity of infection in Vero cells, and was obtained from B. Setton (The Salk Institute). Tissue culture supernatant from infected Vero cells was used as the inoculum to infect COS-1 cells for radiolabeling and immunofluorescence. The multiplicity of infection was approximately 0.1, and infected cells were assayed for IBV-specific polypeptides at 24 and 48 h postinfection.

Preparation of Recombinant Vaccinia Viruses Encoding El and Am1,2

DNA encoding wild-type El or the mutant protein Am1,2 was excised from the SV40 expression vector with Xho I, and the ends filled in with the Klown fragment of DNA polymerase I. The inserts were then subcloned into the vector pSC11 (Chakrabarti et al., 1985) at the unique Sma I site. After selection of clones with inserts in the correct orientation for expression, virions from the vaccinia promoter lytically infected Vero cells, and was obtained from D. Stern (The Salk Institute). Tissue culture supernatant from infected Vero cells was used as the inoculum to infect COS-1 cells for radiolabeling and immunofluorescence. The multiplicity of infection was approximately 0.1, and infected cells were assayed for IBV-specific polypeptides at 24 and 48 h postinfection.

Antibody Preparation

A polyclonal rabbit antiserum was raised to a synthetic peptide corresponding to the carboxy-terminal 22 amino acids of IBV El. The peptide was conjugated to BSA via the penultimate tyrosine residue with bis-diazobenzidine...
(DeCarvalho et al., 1964). Two New Zealand white rabbits were immunized with 1 mg conjugate each, emulsified with 0.75 ml complete Freund's adjuvant in a total volume of 1.5 ml. About 30 sites were injected intradermally with 50 μl per site. Rabbis were boosted with ~0.5 mg conjugate (0.75 ml total) in the same way every 4 wk. ELISA titers to the peptide were measured in a solid-phase assay that uses a second antibody conjugated with hors eradish peroxidase, and were approximately 1:10,000 after the second boost. This titer did not change significantly after repeated boosts. After the second boost, the synthetic peptide was discovered to be incorrect in that it contained an extra glycine (after the glycine at position 8 of the peptide), and subsequent boosts were performed with the correct synthetic peptide. Ability of the antiserum to immunoprecipitate the hybrid protein G23 (Puddington et al., 1986) was detected after the third boost. This titer increased until the fifth boost, when one of the two rabbits was producing antibody with a slightly higher titer than the other with less background in immunoprecipitates. This antiserum was used for all subsequent experiments.

Anti-peptide antibodies were affinity purified on Affigel-histamine coupled columns with the peptide. Histamine was coupled to Affigel 10 (Bio-Rad Laboratories, Richmond, CA); the peptide was then coupled to the conjugated resin via the tyrosine residue with bis-diazobenzidine as described above. 10 μg of peptide was coupled to 1 ml of resin, and remaining active groups were blocked with 1 mg/ml ovalbumin. Serum (4 μl) containing antibodies to the peptide was incubated with 1 ml of conjugated resin for 4 h at 4°C with end-over-end inversion. After transfer to a column, resin was first washed with 20 ml of 10 mM Tris, pH 8.0, with 0.5% deoxycholate, and then with 15 ml of 10 mM Tris, pH 8.0, containing 0.5 M NaCl. Specific antibodies were eluted with 4 M MgCl2 and dialyzed immediately against 0 mM Tris, pH 7.4, containing 0.15 M NaCl and 0.02% NaN3. Pooled fractions with the highest OD280 reading were stored at 4°C with 100 μM kallikrein inhibitor (Calbiochem-Behring Corp., La Jolla, CA) and 0.5 mg/ml ovalbumin. Approximately 1.5 mg of purified immunoglobulin was recovered from 4 ml of serum.

Transfection of COS-1 Cells, Radiolabeling and Immunoprecipitation

COS-1 cells (4 × 105) plated in 35-mm dishes the previous day were transfected with 10 μg supercoiled DNA using DEAE-dextran followed by chloroquine treatment as previously described (Adams and Rose, 1985). Approximately 44 h after transfection, cells were labeled at 37°C in 0.5 μCi [35S]cysteine (>1,300 Ci/mmol; Amersham Corp., Arlington Heights, IL) in 0.5 ml cysteine-free Dulbecco-Vogt's modified Eagle's medium containing 10% dialyzed FCS for 1 h or for the time indicated. For treatment with 2-ME, COS cells were incubated with a final concentration of 0.33 M iodoacetamide for 60 min at room temperature, and proteins were precipitated with 9 vol of acetone at -20°C for 2 h. After washing in acetone, precipitates were dissolved in 1 M Tris, pH 8.8, 2% SDS, and 2% 2-mercaptoethanol.

Treatment of Intact Cells with Proteases

Transfected COS-1 cells were radiolabeled as described above with [35S]cysteine for 90 min, and incubated in the presence of excess unlabeled cysteine for 90 min. Cells were then incubated for 15 min at 37°C in 0.5 ml of PBS containing 1 mg/ml bromelain (Calbiochem-Behring Corp.) and 0.1 mM 2-mercaptoethanol. Parallel dishes of transfected cells were incubated for the same period of time in the absence of bromelain, then lysed as usual. Bromelain-treated cells were collected by centrifugation and washed three times in Tris-buffered saline, lysed, and El proteins were immunoprecipitated as described above. HeLa cells infected with VEEV or VSVIndiana labeled 5 h postinfection with [35S]cysteine for 60 min. As described above, cells were either (a) mock digested for 15 min at 37°C, (b) treated with 1 mg/ml bromelain, (c) treated with 1 mg/ml trypsin-TPCK ( Worthington Biochemical Corp., Freehold, NJ) in PBS, or (d) treated in medium with 1% FCS containing 1 mg/ml pronase (from Streptomyces griseus; Boehringer Mannheim Biochemicals), which had been previously self digested for 15 min at 37°C.

Results

Construction of an Expression Vector Encoding IBV E1

A cDNA clone prepared from viral genomic RNA encoding the IBV E1 protein was obtained from D. Stern (Stern, 1983), and subjected to DNA sequence analysis. This nucleotide sequence predicts a polypeptide of 225 amino acids, and is identical to that for the IBV E1 protein as reported by Bourns nell et al. (1984), with the exception of two nucleotides (Fig. 1; see Materials and Methods). This sequence includes two potential sites for N-linked glycosylation at Asn 3 and Asn 6, both of which are glycosylated in the E1 protein isolated from IBV, since the protein contains two N-linked oligosaccharides (Stern and Sefton, 1986b). In contrast, the MHV E1 protein contains only O-linked carbohydrate (Neumann and Klken, 1981). The three potential membrane-spanning domains of IBV E1 include amino acids Tyr 21 through Thr 42.

Indirect Immunofluorescence Microscopy

COS-1 cells grown on coverslips were fixed with paraformaldehyde and permeabilized with NP-40 as described (Rose and Bergmann, 1983). E1 proteins were detected by incubation with the affinity-purified anti-E1 peptide antibody described above (1:30) followed by affinity-purified fluorescein-conjugated goat anti-rabbit IgG (1:50; Southern Biotechnology Associates, Inc., Birmingham, AL). For localization of the Golgi complex, coverslips were incubated with rhodamine-conjugated wheat germ agglutinin (1:100, E-Y Laboratories, Inc., San Mateo, CA). Cells were visualized with a Nikon Optiphot microscope equipped with fluorescence epilumination and a Nikon 40× oil immersion plan apochromat objective.

Figure 2. Detection of E1 in infected and transfected COS-1 cells. (A) COS-1 cells were either mock-infected or infected with IBV and radiolabeled 48 h later with [35S]cysteine for 2 h. IBV proteins were immunoprecipitated with a rabbit anti-IBV serum (aIBV) or with a rabbit anti-peptide serum specific for the carboxy terminus of IBV E1 (αCTE1). Positions of the IBV proteins N and E1 are noted, and the arrow marks the position of a polypeptide that is most likely the spike glycoprotein, E2. (B) COS-1 cells were transfected with vector alone (pJCl19) or with pSV/IBVE1, and labeled 44 h later with [35S]cysteine for 2 h. E1 was immunoprecipitated with αCTE1. (C) COS-1 cells were infected with a recombinant vaccinia virus encoding IBV E1 (VVE1) or as a control, with a recombinant vaccinia virus encoding VSV G protein (VVG). Cells were labeled 5 h after infection with [35S]cysteine for 1 h, and E1 was immunoprecipitated with αCTE1. Samples in A and C were eluted in sample buffer at room temperature for 20 min, and those in B were eluted at 100°C, followed by alkylation with iodoacetamide (see Materials and Methods). Samples in A and B were subjected to electrophoresis in the same 15% polyacrylamide gel, and samples in C were subjected to electrophoresis in a 10% polyacrylamide gel.

Met 52 through Tyr 72, and Gly 78 through Ile 101 (Fig. 1). A fragment containing the complete coding sequence for IBV E1 was subcloned into the SV40-based expression vector, pJCl19 (Sprague et al., 1983). When transfected onto COS cells, which provide T antigen and thus support extensive replication of the vector (Gluzman, 1981), high levels of protein can be expressed transiently from the late SV40 promoter. Initial attempts to detect the IBV E1 polypeptide in COS-1 cells transfected with this construct (pSV/IBVE1) were unsuccessful. These experiments were performed with a rabbit hyperimmune serum raised to purified virus, which immunoprecipitates IBV E1 from infected chick embryo kidney cells (Stern and Sefton, 1982a). Although E1 could not be detected in transfected COS-1 cells, E1-specific RNA was readily detected in dot blots (data not shown). Inability to detect the protein could have been the result of its instability or toxicity to cells, aberrant splicing from cryptic splice sites, and/or a low titer of antibodies to E1 in the anti-IBV serum. Results obtained with hybrid proteins between IBV E1 and VSV G protein suggested that at least one of the problems was an insufficient titer of antibodies to E1 in the anti-IBV serum (not shown).

Detection of IBV E1 in Transfected Cells using an Anti–Peptide Antiserum

We prepared a rabbit antiserum specific for a synthetic peptide corresponding to the carboxy-terminal 22 amino acids of IBV E1. A peptide corresponding to this region of the polypeptide was chosen because it is likely to be the most accessible in the native protein. COS-1 cells infected with IBV were labeled 48 h after infection with [35S]cysteine, and the cell lysate was subjected to immunoprecipitation with the anti-E1 peptide serum. A single polypeptide of ~32 kD was specifically immunoprecipitated by the anti–E1 peptide serum from IBV-infected cells (Fig. 2 A). In contrast, the anti–IBV serum precipitated the nucleocapsid protein (N) as well as E1 and trace amounts of the spike glycoprotein, E2. The anti–peptide serum was therefore highly specific for IBV E1. COS-1 cells transfected with DNA encoding IBV E1 were labeled 44 h after transfection with [35S]cysteine and subjected to immunoprecipitation. A polypeptide co-migrating with E1 from infected cells was precipitated from COS-1 cells transfected with pSV/IBVE1 but not with the vector pJCl19 lacking the insert encoding E1 (Fig. 2 B). A small amount of a 61-kD protein can also be observed in the immunoprecipitates from transfected cells (Fig. 2 B; see also Fig. 7 A). This band was specific for E1-expressing COS-1 cells, but was not consistently observed. It is probable that it represents a dimer of E1, as the MHV E1 protein has been shown to be susceptible to aggregation, especially when heated in the presence of SDS and reducing agent (Sturman, 1977).

In addition to the transient expression of IBV E1 in COS-1 cells using the SV40-based vector, expression of E1 was also achieved in cells infected with a recombinant vaccinia virus that encodes the protein. This expression system is advantageous since every cell is infected and is thus expressing the protein of interest, and since replication in the cytoplasm eliminates the potential problem of aberrant splicing at cryptic splice sites (see Discussion). Recombinant vaccinia virus encoding IBV E1 under control of an early vaccinia promoter was constructed as described (Mackett et al., 1984; Chakrabarti et al., 1985). COS-1 cells infected with this recombinant virus (VVE1), or one encoding the VSV G protein (VVG), were labeled 5 h after infection with [35S]cysteine, and lysates were subjected to immunoprecipitation with the anti–E1 peptide serum. A polypeptide which comigrates with IBV E1 was readily detected in immunoprecipitates from cells infected with the recombinant virus VVE1, but not from control cells infected with VVG (Fig. 2 C).

Localization of E1 in Transfected Cells by Indirect Immunofluorescence

Localization of the IBV E1 protein in transfected COS-1 cells was compared to that in IBV-infected cells using indirect immunofluorescence microscopy. Cells grown on coverslips were either infected with IBV or transfected with pSV/IBVE1. Cells were fixed and permeabilized 29 h after infection or

44 h after transfection, and E1 was detected by incubation with the affinity-purified anti-E1 peptide antibody followed by a fluorescein-conjugated goat anti-rabbit IgG. The Golgi complex of these cells was localized by staining with rhodamine-conjugated wheat germ agglutinin (WGA). Each set of micrographs shows the same field photographed with the fluorescein (αCTE1) and the rhodamine (WGA) filters. Arrows indicate the Golgi region. Bar, ~10 μm.

**Expression of Mutant E1 Proteins Which Lack Two of the Three Putative Membrane-spanning Domains**

Our goal was to identify a structural feature of E1 that might be responsible for intracellular accumulation of the protein. Results obtained with hybrid proteins of VSV G protein and IBV E1 suggested that the amino-terminal half of E1 might contain this information. The hybrid protein G23, with the extracellular and transmembrane domains of G protein and the cytoplasmic domain of E1 was transported efficiently to the cell surface (Puddington et al., 1986), whereas the reciprocal hybrid protein 23G (with the amino-terminal and hydrophobic domains of E1 and the cytoplasmic domain of G protein) was retained intracellularly like the wild-type E1 protein (data not shown). Oligonucleotide-directed mutagenesis was performed to delete sequences encoding either the second and third or the first and second transmembrane domains. This would be expected to produce proteins with only one membrane-spanning domain (the first or the third hydrophobic region, respectively) with the same membrane orientation as wild-type E1. Two questions regarding the mutant proteins could be asked. First, can the first or third membrane-spanning domain mediate insertion of the protein into the membrane in the absence of the other two hydrophobic domains? Second, what is the effect of removing these regions of the protein on the intracellular accumulation of E1?

Oligonucleotides were designed to loop out regions of the coding sequence to precisely delete membrane-spanning domains and the intervening sequences. The mutagenesis was performed in phage M13 by standard methods (Zoller and Smith, 1982) as described previously (Machamer et al., 1985; Adams and Rose, 1985). A schematic representation of the mutant proteins is presented in Fig. 4. The codon for threonine 42 is fused to that for arginine 102 in the mutant protein that lacks the second and third hydrophobic domains (Δm2,3), such that only the first hydrophobic domain remains. Likewise, the codon for glutamic acid 20 is fused to that for glycine 77 in the mutant protein that lacks the first and second hydrophobic domains (Δm1,2), leaving only the third hydrophobic domain.

After DNA encoding the mutant proteins was subcloned into the expression vector, the desired mutations were confirmed by DNA sequence analysis. COS-1 cells were trans-
Figure 4. Schematic representation of wild-type IBV E1 and mutant proteins lacking two of the three membrane-spanning domains. The model depicts the predicted membrane orientation for the wild-type protein as well as the two mutants generated by oligonucleotide-directed mutagenesis which lack either the second and third hydrophobic domains (Δm2,3) or the first and second hydrophobic domains (Δm1,2). The point at which the coding sequence is fused to create the mutant proteins is also shown.

Figure 5. Expression of the mutant E1 proteins in transfected COS-1 cells. COS-1 cells were transfected with DNA encoding the wild-type E1 protein, or the mutant E1 proteins Δm2,3 or Δm1,2. Cells were labeled 44 h after transfection with [35S]cysteine for 1 h. A parallel set of transfected cells was pretreated with 3 μg/ml tunicamycin (Tm) for 2 h and then labeled in the presence of the same concentration of the drug. E1 proteins were immunoprecipitated with the anti-E1 peptide serum and subjected to electrophoresis in a 15% polyacrylamide gel.

Localization of the Mutant E1 Proteins in Transfected Cells

The intracellular distribution of the mutant E1 proteins was analyzed by indirect immunofluorescence microscopy. COS-1 cells grown on coverslips were fixed and permeabilized 44 h after transfection. E1 proteins were visualized by staining with the affinity-purified anti-E1 peptide antibody, followed by a fluorescein-conjugated second antibody. The results are presented in Fig. 6. The mutant E1 protein with only the first hydrophobic domain (Δm2,3) was localized intracellularly, in a pattern similar to that observed for the wild-type E1 protein. Prominent perinuclear staining as well as some reticular staining was observed for both proteins. However, the other mutant protein with only the third hydrophobic domain (Δm1,2) appeared in a pattern similar to that observed for the wild-type E1 protein. Staining of microvilli is readily detected in cells expressing both Δm1,2 and G23 (Fig. 6). This surprising finding suggested that deletion of the first and second membrane-spanning domains of E1 results in removal of a structural feature of the protein which is essential for its accumulation in intracellular membranes. Since the mutant protein with only the first membrane-spanning domain (Δ2,3) accumulates intracellularly...
like the wild-type protein, the information for retention probably resides in the first hydrophobic domain.

Although the results with indirect immunofluorescence suggested that the mutant protein Δm1,2 was transported to the plasma membrane, we sought a more definitive experiment to prove that the amino terminus of the protein was exposed at the cell surface. This was not possible with immunofluorescence experiments, since our antibody recognizes a determinant found only on the cytoplasmic side of the membrane. This proof was obtained by assessing the sensitivity of the protein to proteolysis when intact, transfected cells were treated with bromelain. The amino-terminal, glycosylated domain of IBV E1 in purified virus was recently shown to be susceptible to digestion with this enzyme (Cavanagh et al., 1986). Transfected COS-1 cells were labeled for 90 min with [35S]cysteine, followed by a 90-min chase period. Cells were then treated with bromelain for 15 min. A parallel set of dishes were incubated in the absence of bromelain. Cells were washed and lysed, and E1 proteins were immunoprecipitated and subjected to electrophoresis in an SDS–polyacrylamide gel. Fig. 7 A shows that both wild-type E1 and the mutant Δm2,3 are unaffected when intact cells are treated with bromelain. However, a proportion of the mutant protein Δm1,2 is digested to a form which migrates slightly faster (arrowhead; ~18 kD) than the nonglycosylated protein, suggesting that a portion of the amino terminus, including the oligosaccharides, has been removed from the protein.

The level of expression of the E1 proteins in transfected COS-1 cells was low, and these cells were fragile and susceptible to lysis during proteolysis. Thus to confirm the result above, we used recombinant vaccinia virus vectors to achieve a higher level of expression, and to allow use of another cell type. A recombinant vaccinia virus encoding the mutant E1 protein Δm1,2 was constructed, and HeLa cells were infected with this virus or the recombinant vaccinia virus encoding wild-type E1. The localization of both of these proteins in infected HeLa cells as determined by indirect immunofluorescence microscopy was identical to that observed in transfected COS-1 cells (data not shown). Cells were labeled 5 h after infection with [35S]cysteine for 60 min, and then mock-treated, or treated with bromelain, pronase, or trypsin. After washing and lysing the cells, E1 proteins were immunoprecipitated and subjected to electrophoresis in an SDS–polyacrylamide gel. As shown in Fig. 7 B, the amino terminus of Δm1,2, but not wild-type E1, is susceptible to digestion with bromelain. The decrease in total amount of protein observed in bromelain-treated cells expressing both wild-type and mutant proteins (in Fig. 7 A and B) was a result of loss of cells and/or cell lysis during the digestion. For this reason, pronase and trypsin were also included in the experiment shown in Fig. 7 B. When intact cells expressing Δm1,2 were digested with pronase, a fragment of similar size to that obtained with bromelain was observed. Trypsin does not cleave the amino terminus of Δm1,2, but since the only cleavage site in the amino-terminal domain is quite close to the membrane (Lys 19), this is not unexpected. Thus, the mutant E1 protein with only the third hydrophobic domain is indeed expressed at the cell surface. In a similar experiment using a chase period, virtually all of Δm1,2 was digested to the smaller form (data not shown), suggesting that this protein is efficiently transported to the plasma membrane.

Discussion

We have shown here that the E1 glycoprotein of the coronavirus IBV accumulates in the Golgi region when expressed in...
from cDNA in transfected cells, as it does in virus-infected cells. Concurrent experiments in this laboratory have shown that the E1 protein from another coronavirus, MHV, also accumulates in the Golgi region when expressed in transfected COS cells (Rottier and Rose, 1987). This indicates that the information for intracellular accumulation must reside in the E1 protein itself, and allows its use as a model for membrane proteins that are retained at this point in the exocytic pathway.

The preparation of an antiserum specific for a synthetic peptide corresponding to the carboxy terminus of IBV E1 was instrumental to our ability to detect E1 in transfected COS-1 cells, since a rabbit antiserum prepared to IBV did not have a sufficient titer of antibodies to E1. The level of expression of IBV E1 obtained with the SV40-based expression vector and COS-1 cells was lower than expected by comparison to the other proteins we have expressed with the same vector (Rose and Bergmann, 1982; Guan and Rose, 1984). Since IBV is an RNA virus which replicates in the cytoplasm of the cell, it is possible that aberrant splicing at cryptic splice sites occurs when the cDNA is introduced into the nucleus. Preliminary experiments using Northern blots suggested that a significant proportion of the E1-specific message in transfected COS-1 cells lacks the 5' half of the coding sequence, including the initiation codon (our unpublished observations). We have obtained higher levels of expression of E1 using a recombinant vaccinia virus vector which replicates in the cytoplasm (Mackett et al., 1984; Chakrabarti et al., 1985), and thus avoids the problem of aberrant splicing. This expression system may therefore be the one of choice for future studies of IBV E1.

In this study, we have gained information on two aspects of intracellular targeting of the E1 protein: that of insertion into membranes and that of intracellular accumulation. Mutant E1 proteins that lacked either the first and second or second and third membrane-spanning domains were generated by oligonucleotide-directed mutagenesis of the coding sequence. We found that the mutant protein with only the first hydrophobic domain (Am2,3) or that with only the third hydrophobic domain (Aml,2) were both inserted into the membrane of the endoplasmic reticulum, since both were glycosylated with N-linked oligosaccharides. Thus, it appears that either the first or the third hydrophobic domain can function as an internal, uncleaved signal sequence. Clearly, the third hydrophobic domain must also function as a membrane anchor because the mutant protein with only this hydrophobic domain is expressed on the plasma membrane. The first hydrophobic domain probably also functions as a membrane anchor, but further experiments using in vitro translation in the presence of microsomes followed by proteolysis would be required to prove this. There are several examples of proteins with a single membrane-spanning domain which serves to mediate membrane insertion as well as to anchor the protein in the lipid bilayer (Pos et al., 1984; Holland et al., 1984; Lipp and Dobberstein, 1986). Also, some
proteins that span the membrane several times have been demonstrated to have more than one internal, uncleaved signal sequence, as shown by site-directed mutagenesis and assessment of membrane insertion in vitro (Friedlander and Blobel, 1985; Mueckler and Lodish, 1986).

The most novel information gained from the mutant E1 proteins concerns the intracellular accumulation of the polypeptide. Deletion of the first and second, but not the second and third, hydrophobic domains resulted in efficient expression of the protein at the cell surface. This is the first demonstration that an intracellular membrane protein can be transported to the plasma membrane after elimination of a particular structural domain. Interestingly, Poruchynsky et al. (1985) have shown that a rotavirus protein normally retained in the endoplasmic reticulum is secreted when a portion of the region presumed to be the membrane anchor is deleted. This hydrophobic region thus appears to contain a signal capable of retaining the rotavirus protein in the endoplasmic reticulum.

The mechanism by which the IBV E1 protein is normally retained intracellularly could be envisioned in two ways: either (a) the lack of positive signal for transport to the plasma membrane or (b) the presence of a signal responsible for intracellular retention. The first explanation, lack of a positive signal for transport to the plasma membrane, seems unlikely. If this were the case, fusion of Glu 20 to Gly 77 to delete the first and second hydrophobic domains would have to create a positive signal for transport. We therefore favor the hypothesis that IBV E1 possesses a signal for retention in the Golgi region. This could be an active type of signal, where a specific sequence is recognized by another protein or lipids which are specifically retained in this region of the cell. Alternatively, the retention could be passive, resulting from structural properties of the protein which sterically constrain it from moving in the exocytic pathway, perhaps by inability to be incorporated into transport vesicles. The transport of E1 to the plasma membrane after removal of a retention signal would result if all membrane proteins move passively by bulk flow unless specifically held back. Alternatively, the protein could possess a positive signal for transport to the plasma membrane as well as a signal for intracellular retention, the latter being stronger. Removal of the retention signal would then result in transport of the protein to the plasma membrane. Further experiments designed to determine if signals for transport to the plasma membrane exist in other domains of E1 should allow us to distinguish these possibilities.

The intracellular accumulation of E1 in coronavirus-infected cells results in budding of virions from intracellular membranes. This offers an important advantage to the virus in evasion of the host immune system. Persistent infections are readily established by coronaviruses both in vivo and in vitro (reviewed by Sturman and Holmes, 1983). Perhaps conversion of the E1 protein from a plasma membrane protein to one that is retained intracellularly was an important step in the successful evolution of the coronaviruses. Such a conversion could have logically occurred by incorporation of a retention signal into a protein which already possessed signals for transport to the plasma membrane.

In comparing the sequences of the E1 proteins from MHV and IBV, Rottier et al. (1986) observed that one of the most conserved regions between these proteins is found in the first and second hydrophobic domains. This implies that this region plays an important role in the function of the polypeptide. Our results suggest that this function is the retention of the protein in the Golgi region of the cell. The elucidation of the mechanism by which this occurs should provide valuable clues to the complex process of intracellular transport and targeting of proteins.

We thank Drs. David Stern and Bart Sefton for the cDNA clone encoding IBV E1 and for the rabbit anti-IBV antisera; Nicholas Ling for the synthetic peptide; Bernard Moss for pSC11 and wild-type vaccinia virus; Gail Wertz for advice on selecting recombinant vaccinia viruses; and Bart Sefton, Lynn Puddington, Willy Spaan, Bob Florkiewicz, and Peter Rottier for helpful discussions.
