Novel coronavirus and severe acute respiratory syndrome

“The terror of the unknown is seldom better displayed than by the response of a population to the appearance of an epidemic, particularly when the epidemic strikes without apparent cause”. This quote from 1977 by Edward Kass, describing the fears surrounding the newly recognised legionnaires’ disease, aptly describes the public response to the recent appearance of an unexplained atypical pneumonia referred to as severe acute respiratory syndrome (SARS).

In today’s Lancet, Joseph Peiris and colleagues provide strong evidence that SARS is associated with a novel coronavirus that has not been previously identified in human beings or animals, and begin the process of eliminating the many unknowns from this new syndrome (figure). The investigators used classic viral culture and serological techniques, as well as modern molecular genetic methods, to characterise and to determine the cause of the disease in 50 patients with SARS in Hong Kong. One of the strengths of their report, and an important means of establishing causality, is their analysis of specimens from control patients. None of 40 respiratory secretions from patients with other respiratory diseases contained coronavirus RNA, and none of 200 serum samples from blood donors had serum antibody to this new coronavirus. These findings significantly strengthen the tentative aetiological association reported by other investigators from the Centers for Disease Control and Prevention (CDCP) in Atlanta and from Toronto, who have also isolated a novel coronavirus from patients with SARS. As other pathogens, such as human metapneumovirus and Chlamydia spp, are identified in SARS patients, it will be important to use control groups to determine their role in causality or as cofactors for severe disease.

The clinical features associated with SARS are rapidly becoming available through Peiris’ and other reports. The Hong Kong investigators identified five clusters of patients by using a modified WHO case definition for SARS, and describe the clinical manifestations of this serious disease. It is notable that nearly 40% of the patients developed respiratory failure that required assisted ventilation. Clinical descriptions will be important in modifying the case definition of this syndrome should it spread, as is likely, beyond the tightly linked clusters that have characterised the epidemiology of SARS thus far. Unfortunately, the early clinical appearance may not allow ready distinction from other common winter-time respiratory viral infections. However, certain characteristics of SARS are noteworthy. The constellation of absence of upper respiratory symptoms, the presence of dry cough, and minimal auscultatory findings with consolidation on chest radiographs may alert the clinician to the possible diagnosis of SARS. The presence of lymphopenia, leucopenia, thrombocytopenia, and elevated liver enzymes and creatinine kinase may also raise suspicion.

Clinical diagnosis will become particularly problematic once the association with travel or case contact is lost. Thus, rapid and accurate diagnostic tools will be critical in the management of this epidemic. Given the experience with other respiratory viruses, it is likely that culture and direct antigen-detection from respiratory secretions will not suffice in view of the lethality and contagious nature of this new agent. Rapid diagnosis of SARS, which is important for infection-control measures and potential treatment,
Severe acute respiratory syndrome (SARS) has recently been recognised as a newly emerging infectious disease that is highly contagious with significant morbidity and mortality. The first index case in Hong Kong was admitted on Feb 22, 2003. As of April 6, 842 cases have been identified in Hong Kong, with fatal complications in 22 patients. The outbreak has prompted the Hospital Authority of Hong Kong and the Department of Health to implement a series of public-health measures and hospital policies for the diagnosis and management of patients with SARS.

The figures are summaries of the management flowchart in the accident and emergency department for patients with a history of definite contact with SARS patients within the past 10 days (figure 1) and for patients with no such definite contact (figure 2).

The Hong Kong Hospital Authority SARS Command Centre has been established to coordinate clinical activities, including identification and reporting of cases, implementation of infection-control measures, dissemination of information to the public, development of diagnostic tests, and assessment of treatment regimens in a cluster network of hospitals. Each hospital cluster has designated treatment centres. The Hospital Authority and the Department of Health are working collaboratively with the two universities (the Chinese University of Hong Kong and the University of Hong Kong) and with international agencies to identify the aetiological agent(s)
