γδ T cells mediate demyelination in athymic (nude) mice infected with the neurotropic coronavirus mouse hepatitis virus strain JHM. Now, we show that these cells also mediate the same process in mice lacking αβ T cells (T-cell receptor β-deficient [TCRβ−/−] mice) and demyelination is gamma interferon (IFN-γ) dependent. Most strikingly, our results also show a major role for NKG2D, expressed on γδ T cells, in the demyelinating process with in vivo blockade of NKG2D interactions resulting in a 60% reduction in demyelination. NKG2D may serve as a primary recognition receptor or as a costimulatory molecule. We show that NKG2D+ γδ T cells in the JHM-infected central nervous system express the adaptor molecule DAP12 and an NKG2D isoform (NKG2D short), both required for NKG2D to serve as a primary receptor. These results are consistent with models in which γδ T cells mediate demyelination using the same effector cytokine, IFN-γ, as CD8 T cells and do so without a requirement for signaling through the TCR.

The human disease multiple sclerosis is an immune-mediated, multifocal demyelinating disease of unknown etiology (38). T cells, B cells, and macrophages/microglia can all be found in the lesions of multiple sclerosis (26). However, the specific role of the many immune system components in the human demyelinating process is only partially understood.

In rodents, the histopathology of multiple sclerosis is, in part, modeled by a number of virus-induced demyelinating diseases, including those induced by infection with mouse hepatitis virus strain JHM (55). As with multiple sclerosis, the disease induced by JHM is largely immune mediated (23). Mice with severe combined immunodeficiency (SCID mice) or mice lacking recombination activation gene 1 (RAG1−/− mice), both of which lack B and T cells, did not develop demyelination upon infection with JHM (6, 28, 60). T cells but not B cells were sufficient to mediate demyelination as recipients of IFN-γ−/− CD8 T cells (44). In contrast, infected recipients of IFN-γ−/− CD4 T cells developed greater amounts of demyelination than their counterparts that received IFN-γ+/+ CD4 T cells, suggesting that, in the context of CD4 T cells, IFN-γ may be acting to down-regulate the immune response (43). These results are in agreement with those obtained from other experimental models, as IFN-γ−/− or IFN-γ receptor-deficient mice with CD4 T-cell-mediated EAE developed more severe disease than wild-type mice whereas neutralization of IFN-γ diminished EAE in models in which demyelination was CD8 T-cell dependent (13, 30, 56, 59).

γδ T cells have been identified in demyelinating lesions in the central nervous system (CNS) of patients with multiple sclerosis (50, 53). They have also been identified in rodents with EAE, although their function in these animals is controversial. Depletion of γδ T cells resulted in more severe disease or an inability to resolve EAE in one set of studies (34, 45). However, in other studies, the absence of γδ T cells resulted in milder disease (39, 47, 54). These different outcomes are explained in part by differences in experimental protocols. For example, two groups recently showed that inflammation was diminished during the early stages of EAE in the absence of γδ T cells (39, 45). While disease resolved if cells were transferred into normal mice, it did not if the recipient mice lacked γδ T cells (45). Thus, in the early stages of disease, the absence of γδ T cells resulted in milder disease, but their absence during the resolution stage resulted in more severe disease. However, in none of these models was the role of γδ T cells examined in the absence of αβ T cells.

The mechanisms by which γδ T cells are activated or function in the setting of demyelination, including that induced by
JHM, remain unknown. No antigen-presenting molecule for γδ T cells, such as major histocompatibility complex class I and II molecules, has been identified. In common with CD8 T and NK cells, γδ T cells are able to lyse target cells and to produce IFN-γ in response to both infectious and tumor antigens (7, 17, 19, 58). Few ligands for murine γδ T cells have been identified and there is no identifiable molecular pattern among these putative ligands. Many of these ligands are proteins involved in splicing from a single gene and differ by 13 amino acids in their NH₂ termini. The long form (NGK2D-L) is present in naive cells, whereas the short form (NGK2D-S) is detected only in activated cells (19). In one study, cutaneous γδ T cells were shown to recognize two major histocompatibility complex class I-related molecules, Rae-1 and H60, via the activating NK receptor NGK2D (19). These NGK2D-ligand interactions resulted in activation of the cytolytic functions of γδ T cells and thereby effected a response to cutaneous malignancy (2, 19). In addition, γδ T cells have been demonstrated to express down-regulatory molecules of the Ly49 family (22, 57), suggesting that these cells function more in the innate immune response than do traditional αβ T cells.

In NK cells, NGK2D may serve as a primary activating receptor, with cross-linking of the receptor sufficient for full cellular activation (48). This process involves signaling through DAP12 (DNAX-activating protein of 12 kDa), an adaptor molecule that contains a cytoplasmic immunoreceptor tyrosine-based activation motif. DAP12 is associated only with the short variant of NGK2D (NGK2D-S) (19). NK cells also express the adaptor protein DAP10 (DAP of 10 kDa), a protein that has motifs resembling those found in costimulatory molecules such as CD28 (16, 18). Activation via this adaptor molecule is not believed to serve as a primary activating signal but rather to provide costimulatory activity. This differentiation between involvement of DAP10 in primary stimulatory and costimulatory pathways is not complete, however, since recent data suggest that DAP10 signaling is sufficient for some aspects of NK activation (64). In contrast to NK cells, CD8 T cells, which also express both isoforms of NGK2D, cannot be fully activated by cross-linking of the receptor. These cells express DAP10 but no DAP12, indicating that in the absence of DAP12, NGK2D serves only as a costimulatory receptor in this cell type. In support of this, expression of DAP12 by CD8 T cells from a transgene facilitates cellular activation by NGK2D ligation (16). Herein, we investigate the roles of IFN-γ and NGK2D in γδ T-cell-mediated demyelination.

**MATERIALS AND METHODS**

**Mice.** Specific-pathogen-free TCRα/TCRβ−/− (backcrossed 12 times onto a C57BL/6 background, as per the vendor) and C57BL/6 mice were purchased from Jackson Laboratories (Bar Harbor, ME) and bred at the University of Iowa. Mice were assessed for clinical disease using the following scale: 0, asymptomatic; 1, limp tail; 2, wobbly gait or hunch or mild encephalitis; 3, hindlimb paresis or moderate encephalitis; 4, quadriparesis/paralysis or severe encephalitis; 5, moribund. In all experiments, mice were euthanized 14 days postinfection with JHM. All animal studies were approved by the University of Iowa Animal Care and Use Committee.

**Viruses.** We used the neuroattenuated variant of MHV JHM, strain 2.2-V-1, provided by J. Fleming (University of Wisconsin, Madison, WI), in all experiments. Mice were infected with 1,000 PFU of JHM intracerebrally. Viruses were titrated by plaque reduction assay as previously described (42).

**Flow cytometry.** Staining for γδ T cells and phenotypic markers was done as previously described (14). In brief, we made a single-cell suspension from the brains of JHM-infected mice and isolated leukocytes using a 30% Percoll (Pharmacia, Uppsala, Sweden) gradient. We blocked with treatment with 10% normal rat serum (Pel-Freez Biologicals, Rogers, AR) and 1:200 anti-IFN-γ (monoclonal antibody 2.4G2; BD Pharmingen, San Diego, CA). Cells were then stained with fluorescein isothiocyanate- or phycoerythrin-conjugated anti-γδ TCR (monoclonal antibody GL3) and anti-CD44 (monoclonal antibody IM-7), anti-CD62L (monoclonal antibody MEL-14), anti-CD69 (monoclonal antibody H1.2F3) (all from Pharmingen) or phycoerythrin-conjugated anti-NGK2D (monoclonal antibody CX5; eBioscience, San Diego, CA). Cells were washed and fixed with Cytofix (Pharmingen). A FACScan (Becton-Dickinson, Mountain View, CA) was used to analyze stained cells.

**Depletion by antibody.** IFN-γ was depleted in vivo by administration of 750 μg of the anti-IFN-γ monoclonal antibody XMG1.2 (obtained from John Harty, University of Iowa) on days 0, 2, 5, 8, and 11 postinfection. The isotype-matched irrelevant antibody HJPC-1 (a gift from M. Dailey, University of Iowa) was used as a control. For blockade of CD154, we treated mice with 150 μg of monoclonal antibody MR-1 on the day of infection and every 3 days thereafter. For blockade of NGK2D, we treated mice with 250 μg of hamster anti-mouse NGK2D monoclonal antibody C7 (a gift from Wayne Yokoyama, Washington University, and Jon Heusel, University of Iowa) on days 0, 3, 6, 9, and 12 postinfection (27). γδ T cells were depleted with 250 μg of UC7-13DS as previously described (14). As a control for treatment with either MR-1, C7, or UC7-13DS, we treated mice with equal quantities of hamster immunoglobulin (Ig) (Jackson Immunoresearch, West Grove, PA).

Depletion of NK cells was performed using an anti-NK1.1 antibody (clone PK-136, obtained from Jon Heusel and Tim Ratliff, University of Iowa). The antibody was administered at an initial dose of 200 μg 1 day prior to infection and at maintenance doses of 100 μg every 3 days until harvest. An isotype-matched control antibody (Sigma, St. Louis, MO) was used at the same concentrations. Efficacy of depletion was monitored by flow cytometry using monoclonal antibodies to CD3 (clone 145-2C11, Pharmingen) and NGK2D (NK cells are NK2D−/−NK1.1+ NK2D+−) and by cytotoxicity assays, using YAC-1 target cells in chromium release assays (9). Depletion was greater than 90% by flow cytometry. At an effector-to-target cell ratio of 25:1, residual NK cell cytotoxicity in depleted animals was less than 3% of that detected in controls.

**Immunohistochemistry and immunofluorescence.** Spinal cords from JHM-infected mice were fixed, frozen in formalin (Labcso, Solon, OH), and embedded in paraffin. After blocking with CaseBlock (Zymed, South San Francisco, CA), 8-μm sections were incubated with anti-JHM nucleocapsid monoclonal antibody SB188.2 (a gift from Michael Buchmeier, Scripps Research Institute, La Jolla, CA), anti-F4/80 monoclonal antibody A3-1 (Serotech, Oxford, England), or a cocktail of anti-neurofilament monoclonal antibodies (SMM-312, Sternberger Monoclonal Antibodies, Lutherville, MD). For immunohistochemistry, samples were incubated with biotinylated anti-mouse IgG (for anti-JHM-N; Jackson Immunoresearch) or anti-rat IgG (for F4/80; Vector, Burlingame, CA) and developed with streptavidin-horseradish peroxidase (Jackson Immunoresearch) and diaminobenzidine (Sigma). For immunofluorescence, fluorescein isothiocyanate-conjugated anti-mouse IgG (Vector) was used.

**Quantification of demyelination and macrophages.** Demyelination was quantified as previously described. In brief, 8-μm sections of zine formalin-fixed, paraffin-embedded spinal cords were stained with Luxol fast blue and counterstained with hematoxylin and eosin. Sections were photographed using an Olympus (Goleta, CA) digital camera. The total area of intact myelin and demyelinated areas was quantified using NIH ImageJ. Macrophage infiltration into the white and gray matter was determined by counting F4/80+ cells in eight noncontiguous fields under 10X magnification as previously described (14).

**RT-PCR for DAP10, DAP12, and NGK2D.** To determine whether mRNA for DAP10, DAP12, or NGK2D were expressed in CNS-infiltrating γδ cells, we used nested reverse transcription (RT)-PCR. NGK2D−/− γδ or CD8 T cells were isolated using flow cytometric sorting on a FACSDiva (Becton-Dickinson, Mountain View, CA). RNA was recovered from these cells using an RNeasy column kit.
concanavalin A supernatant, and 50 mM were resuspended in RPMI supplemented with 10% fetal calf serum, 5% rat anti-NKG2D monoclonal antibody (clone A10. eBioscience, San Diego, CA) at room temperature, washed with phosphate-buffered saline, and incubated with coated plates. Samples were then incubated and analyzed as described above.

**RESULTS**

In our previous study, we demonstrated that demyelination in nude mice was mediated by γδ T cells. Because the defect in these mice is a poorly characterized genetic defect that results in the lack of a thymus, conventional αβ T cells emerge in detectable numbers beginning at approximately 10 weeks of age (32). Although these cells did not contribute to demyelination at the age we studied, we were concerned that the presence of these cells could potentially confound further studies. To avoid this potential problem, we analyzed demyelination in JHM-infected mice lacking the TCRβ chain. These mice do not express αβ TCRs, so cells of the T-cell lineage are only capable of expressing the γδ TCR.

γδ T cells mediate demyelination in TCRβ−/− mice. Initially, we characterized the disease induced by JHM infection in TCRβ−/− mice. These mice survived for up to 16 to 18 days postinfection, which was on average longer than JHM-infected nude mice (14). However, because mice began to die at day 14 postinfection, we analyzed mice at this time point in all experiments to ensure uniform comparisons.

**FIG. 1.** Progression of clinical disease and demyelination in JHM-infected TCRβ−/− mice is dependent on γδ T cells and expression of IFN-γ and NKG2D. (A) TCRβ−/− mice were infected with JHM and treated with anti-γδ TCR monoclonal antibody UC7-13D5 (n = 7, open squares), anti-IFN-γ monoclonal antibody XMG1.2 (n = 7, solid diamonds), anti-CD154 monoclonal antibody MR-1 (n = 4, hatched squares), or anti-NKG2D monoclonal antibody C7 (n = 8, hatched diamonds). Clinical signs were monitored as described in Materials and Methods. Mice that were not treated with antibody (n = 6, solid triangles) or were treated with control antibody (n = 20, open circles) developed the most severe disease. Each antibody was analyzed in at least two independent experiments. Samples were analyzed for statistical significance by comparing pairs of values at each day postinfection. Differences between mice receiving hamster Ig and those receiving anti-γδ TCR monoclonal antibody, anti-IFN-γ monoclonal antibody, or anti-NKG2D monoclonal antibody were statistically significant (day 5: P < 0.05; days 6 and 7: P < 0.01; days 8+: P < 0.001). The difference between treatment with anti-NKG2D monoclonal antibody and anti-IFN-γ monoclonal antibody or anti-γδ TCR monoclonal antibody was also statistically significant (day 7: P < 0.01; days 8+: P < 0.001). The clinical course after anti-IFN-γ monoclonal antibody versus anti-γδ TCR monoclonal antibody treatment was not significantly different (P > 0.05). (B) Demyelination was initially detectable between days 7 and 10 postinfection in JHM-infected TCRβ−/− mice.

Demyelination in TCRβ−/− mice requires IFN-γ. We next sought to address the mechanisms by which γδ T cells induce demyelination in TCRβ−/− mice. Demyelination induced by CD8 T cells in JHM-infected mice is dependent on production of IFN-γ (44). Given similarities between NK cells, CD8 T cells, and γδ T cells in effector functions, in particular cytotoxicity and IFN-γ molecule expression (25), we reasoned that IFN-γ was likely to be a critical molecule in the demyelinating process. To test this hypothesis, TCRβ−/− mice were infected with JHM and treated with the depleting anti-IFN-γ monoclonal antibody XMG1.2 or a control antibody, as described in Materials and Methods.

TCRβ−/− mice treated with monoclonal antibody XMG1.2 exhibited a disease course different from that of mice treated with control antibody but nearly identical to that observed in mice treated with anti-γδ TCR antibody (Fig. 1A). These mice in general failed to develop clinical signs of demyelination but instead only had signs of mild encephalitis, such as hunching, irritability, lethargy, and ruffled fur. Consistent with the clinical
signs, anti-IFN-γ antibody treatment resulted in an 80% reduction (4.2 ± 1.6% versus 20.7 ± 5.3%) in the amount of demyelination observed compared to control mice (Table 1). These results demonstrated that IFN-γ was necessary for demyelination in TCRγδ−/− mice. We also observed minimal infiltration of macrophages/microglia into the white matter of JHM-infected, monoclonal antibody XMG1.2-treated TCRγδ−/− mice (data not shown), consistent with a role for these cells in the demyelinating process.

Collectively, these results suggest that γδ T cells mediate demyelination via an IFN-γ-dependent mechanism. Consistent with this conclusion, we also demonstrated that CNS-derived and splenic γδ T cells from JHM-infected mice produced IFN-γ in response to phorbol myristate acetate and ionomycin (Fig. 4). IFN-γ is also produced by NK cells, but these cells are unlikely to be the source for the IFN-γ involved in demyelination. RAG1−/− mice contain normal numbers of NK cells, but demyelination does not occur in JHM-infected RAG1−/− mice in the absence of experimental interventions (44). To prove formally that NK cells were not critical for demyelination, we depleted these cells from JHM-infected TCRγδ−/− mice. Depletion of NK cells had no effect on the amount of demyelination (Table 1). Failure to identify a target in JHM for γδ T cells. We were unable to identify a JHM-specific target for γδ T cells in infected TCRγδ−/− mice. In several experiments, we variably incubated CNS-derived γδ T cells from infected mice with either preparations of inactivated virus, structural proteins derived from JHM, or JHM-infected cell lysates. We used analogous methods to identify CD4 and CD8 αβ T-cell epitopes (10, 36, 62). However, we consistently observed no activation of γδ T cells above baseline as measured by either IFN-γ or tumor necrosis factor alpha production (data not shown). Although these data do not rule out direct recognition of JHM antigen by γδ T cells, they are consistent with previous data showing that γδ T cells often recognize host proteins that are upregulated during pathological conditions (24).

Based on these results, we pursued the hypothesis that the γδ T cells were activated, at least in part, through one of their NK cell-activating receptors. Although there are many such activating receptors, NKG2D is the most widely expressed among γδ T cells (48) and we showed that it was expressed on a fraction of γδ T cells in the JHM-infected CNS (Fig. 3F). We next asked whether demyelination was dependent on this mol-

FIG. 3. Phenotype and depletion of γδ T cells. (A and B) JHM-infected mice were treated with hamster Ig (A) or anti-γδ-TCR monoclonal antibody UC7-13D5 (B) on days 6, 3, 6, 9, and 12 postinfection. At 14 days postinfection, γδ T cells constituted 10 to 20% of the lymphocyte infiltrate into the CNS (A). No γδ T cells were detectable in UC7-13D5-treated mice (B). (C to F) Brains were removed from JHM-infected TCRβ−/− mice and CNS-derived lymphocytes were stained with anti-γδ-TCR and antibodies against CD69 (C), CD62L (D), CD44 (E), and NKG2D (F). Most γδ T cells within the CNS had marker levels consistent with an activated phenotype: CD44+, CD62L−, and CD69+. Approximately 40% of γδ T cells expressed the NK activating receptor NKG2D (F). Numbers indicate the percentage of γδ T cells in each group.

FIG. 4. IFN-γ production by CNS-derived and splenic γδ T cells. Lymphocytes were harvested from the spleens (A and B) and CNS (C and D) of infected TCRβ−/− mice at 14 days postinfection. Cells were either treated with phorbol myristate acetate and ionomycin directly ex vivo (B and D) or not stimulated (A and C) and then analyzed for intracellular IFN-γ production as described in Materials and Methods.
controls (Table 1). Treatment with anti-NKG2D antibody resulted in a significant reduction in the amount of demyelination (Table 1) compared to the control limb (7.0 ± 3.1% versus 19.7 ± 4.3%). Notably, demyelination was not completely abrogated, indicating that NKG2D γδ T cells contributed to demyelination in the JHM-infected mouse.

NKG2D is expressed on several other cell types, including macrophages. Because macrophages and microglia are critical for demyelination (33, 55), we next addressed the possibility that macrophage/microglia and not γδ T-cell expression of NKG2D was important in myelin destruction. To do this, we infected C57BL/6 mice with JHM and treated them with C7 or hamster Ig as described above. Demyelination in these mice is mediated largely by CD4 and CD8 γδ T cells (23). Only a subset of CNS-derived CD8 T cells in these mice express NKG2D at 14 days postinfection (Fig. 5C), a time when most anti-JHM CD8 T cells in the infected CNS have lost cytolytic activity (5). NKG2D expression was not detected on these cells after anti-NKG2D monoclonal antibody treatment (Fig. 5E), showing the efficacy of the antibody treatment. There was no difference in the amount of demyelination observed between C7- and Ig-treated wild-type mice (16.1% versus 15.7%, respectively, Table 1). These results indicate that depletion of NKG2D + macrophages did not contribute to the reduction of demyelination in anti-NKG2D monoclonal antibody-treated C57BL/6 mice. They suggest that the key effect of anti-NKG2D antibody treatment in TCRβ−/− mice is to diminish γδ T-cell and not macrophage function and thereby to prevent demyelination.

CD40-CD154 interactions have been implicated in the pathogenesis of CNS inflammation in the experimental autoimmune encephalitis model (3) and CD154 is expressed by γδ T cells (7). To investigate the potential role of these interactions in demyelination induced by γδ T cells in JHM-infected mice, we treated mice with the anti-CD154 monoclonal antibody MR-1 as described in Materials and Methods. Treatment with this antibody did not result in a change in the amount of demyelination (Table 1) or clinical disease (Fig. 1A), suggesting that CD40/CD40L interactions were not critical for γδ T-cell-mediated demyelination.

DAP12 and NKG2D-S mRNAs are expressed in NKG2D + γδ T cells in the CNS. The adapter signaling proteins DAP10 and DAP12 associate with NKG2D in NK cells (48) and DAP12 is expressed by at least some splenic γδ T cells (41). Cross-linking NKG2D is sufficient by itself to activate NK cells with signaling occurring via DAP12-dependent pathways (16). To probe the expression of DAP10 and DAP12 in NKG2D + γδ T cells within the CNS, we used nested RT-PCR to identify mRNA expression. We sorted NKG2D + γδ T cells from the JHM-infected TCRβ−/− CNS. As a control, we also sorted NKG2D + CD8 T cells from the spleens of uninfected C57BL/6 mice. RNA was harvested from these cells and subjected to RT-PCR as described in Materials and Methods. NKG2D + γδ T cells from three independent samples all showed evidence of both DAP12 and DAP10 mRNAs, while CD8 T cells derived from C57BL/6 mice expressed DAP10 but not DAP12 (Fig. 6A). DAP12 is associated with NKG2D-S but not NKG2D-L. As shown in Fig. 6B, NKG2D-S mRNA is expressed in CNS-derived NKG2D + γδ T cells. These results suggest that the...
pathway for complete activation is present in these CNS-derived γδ T cells.

**DISCUSSION**

In this study, we confirmed and extended our previous finding that γδ T cells mediate demyelination. In both nude mice and TCRβ−/− mice, infection with JHM results in a robust γδ T-cell infiltrate, with subsequent activation of macrophages and microglia, resulting in demyelination. Furthermore, we have begun to elucidate the mechanisms by which these cells induce demyelination. γδ T cells, like CD8 T cells, induce demyelination by an IFN-γ-dependent mechanism. Most importantly, NKG2D+ T cells are critical for virus-induced demyelination and are consistent with previous results indicating a role for this receptor molecule in autoimmune diabetes (40).

The function of murine γδ T cells remains largely elusive. In humans, γδ T cells appear to increase in number after infection with a number of bacterial agents, including mycobacteria and rickettsiae, and various γδ T-cell nonpeptide target antigens have been identified (37). No such antigenic patterns have been found in mice, although, in one case, murine γδ T cells have been shown to interact with herpes simplex virus glycoprotein I (51, 52). This interaction did not require antigen presentation by major histocompatibility complex class I or II molecules. Likewise, few descriptions of a pathogenic role for γδ T cells exist. In mice with EAE, depletion of γδ T cells resulted in decreased IFN-γ expression by αβ T cells in the CNS, with effects on both the initiation and resolution of disease (39, 45). Disease outcome was worse when γδ T cells were not present during the resolution phase (45). The absence of these cells during the initial stages resulted in less severe disease with a concomitant reduction in the levels of several proinflammatory cytokines and chemokines (39, 46, 47).

In our experiments, treatment with anti-IFN-γ antibody resulted in an 80% decrease in γδ T-cell-mediated demyelination (Table 1). Although γδ T cells act, in part, to regulate IFN-γ production by αβ T cells in mice with EAE (39, 45), we think that it is more likely that IFN-γ produced by γδ T cells is directly involved in the demyelinating process in JHM-infected RAG1−/− mice since these mice lack αβ T cells and γδ T cells from the infected CNS are able to express IFN-γ (Fig. 4). Also, it is unlikely that IFN-γ production by NK cells is required for demyelination, since depletion of NK cells did not diminish the amount of demyelination that we detected (Table 1).

IFN-γ expressed by γδ T cells may directly activate macrophages/microglia, cells which are important for demyelination. Alternatively, these cells may interact with infected target cells in the CNS to release proinflammatory cytokines or chemokines. The latter would then serve as chemoattractants for macrophages/microglia and thereby propagate the demyelinating process. Expression of chemokines such as CCL2/monocyte chemotactic protein 1 and CCL3/macrophage inflammatory protein 1α has been identified as crucial for macrophage/microglia infiltration in EAE (29, 35, 63). CCL5 (RANTES)/CCR5 and CCL2/CCR2 interactions were identified as important in T-cell and macrophage infiltration into the JHM-infected CNS (12, 20). Consistent with these reports, we recently showed that infection of RAG1−/− mice with a recombinant JHM that expressed CCL2 resulted in demyelination in the absence of any other experimental interventions (33).

In addition to the critical role for IFN-γ in demyelination in TCRβ−/− mice, our results suggest that NKG2D+ γδ T cells play a central role in effecting demyelination. Mice treated with the anti-NKG2D monoclonal antibody exhibited diminished infiltration of macrophages and microglia into the white matter (data not shown). In mice, NKG2D binds to members of the retinoic acid-inducible early transcript 1 (Rae-1) family, to H-60, a minor histocompatibility antigen, and to murine UL16 binding-protein-like transcript 1 (MULT-1), a homologue of a human cytomegalovirus protein (8, 11). Of note, H-60 is not expressed in C57BL/6 mice (15, 48). Rae-1 is detected in the CNS on some neurons, particularly dorsal ganglia (1); our results show that demyelination is primary so that Rae-1, if it is the relevant ligand, would also need to be expressed on another cell type, such as oligodendrocytes or macrophages/microglia.

Notably, a recent study demonstrated that macrophages upregulate Rae-1 upon stimulation through Toll-like receptors, but not through treatment with IFN-γ (21). This raises the intriguing possibility that macrophages and γδ T cells in the JHM-infected TCRβ−/− CNS act in concert to activate each other, leading to demyelination. Our results also show incomplete abrogation of demyelination after NKG2D blockade (Table 1). This result is not unexpected since only a fraction of γδ T cells in the JHM-infected CNS express NKG2D (Fig. 3) and suggests that γδ T cells are also activated via NKG2D-indepen dent mechanisms. These results are in agreement with others showing that NK cell lysis of tumor cells expressing NKG2D ligands is only partially blocked by anti-NKG2D antibody treatment (31).

These results, in conjunction with the detection of DAP12 in γδ T cells, raise the possibility that these cells are activated directly through NKG2D in JHM-infected TCRβ−/− mice. In the case of NK cells, cross-linking NKG2D results in cell activation as measured by cytokine expression and cytotoxicity (31). This process requires DAP12 and the short isomer of NKG2D (16). The presence of the mRNA encoding these 2
molecules within CNS-localized NKG2D* γδ T cells (Fig. 6) suggests a mechanism by which the requirement for TCR recognition of an antigen might be bypassed in these cells.

Collectively, our results provide additional evidence that IFN-γ is critical for demyelination to occur and also are consistent with the notion that γδ T-cell activation in the JHMV-infected mouse occurs via a mechanism, ligation of the NKG2D receptor, which does not involve recognition of a viral antigen. γδ T cells appear to have primarily a regulatory role in rodents with EAE (39, 45). Our results suggest that γδ T cells also function as effector cells in the demyelinating process. These results may be relevant for understanding the role of γδ T cells in multiple sclerosis and, together with previous reports in the EAE model, raise the possibility that γδ T cells have both regulatory and effector roles in the CNS of affected humans.

ACKNOWLEDGMENTS

We thank Jon Heusel and Julienne Grant for helpful discussions and Taeo Kim and Andrew Brooks for review of the manuscript. This research was supported in part by grants from the N.I.H. (NS40438) and National Multiple Sclerosis Society (RG2864). A.A.D. was supported by an individual National Research Service Award from the N.I.H. (NS42981).
