Received 3 September 2003/Accepted 5 July 2004

Phosphorylation of the coronavirus nucleoprotein (N protein) has been predicted to play a role in RNA binding. To investigate this hypothesis, we examined the kinetics of RNA binding between nonphosphorylated and phosphorylated infectious bronchitis virus N protein with nonviral and viral RNA by surface plasmon resonance (Biacore). Mass spectroscopic analysis of N protein identified phosphorylation sites that were proximal to RNA binding domains. Kinetic analysis, by surface plasmon resonance, indicated that nonphosphorylated N protein bound with the same affinity to viral RNA as phosphorylated N protein. However, phosphorylated N protein bound to viral RNA with a higher binding affinity than nonviral RNA, suggesting that phosphorylation of N protein determined the recognition of virus RNA. The data also indicated that a known N protein binding site (involved in transcriptional regulation) consisting of a conserved core sequence present near the 5′ end of the genome (the leader sequence) functioned by promoting high association rates of N protein binding. Further analysis of the leader sequence indicated that the core element was not the only binding site for N protein and that other regions functioned to promote high-affinity binding.

Avian infectious bronchitis virus (IBV) is a member of the Coronaviridae (order Nidovirales) (9), members of which are enveloped viruses with single-stranded, positive-sense RNA genomes that are 5′ capped and 3′ polyadenylated (30, 63). The 5′ two-thirds of the coronavirus genome encodes the replicase gene producing two polyproteins, Rep1a and RepLab, the latter resulting from a −1 frameshift (7). The remaining proteins, which include the nucleoprotein (N), are expressed from a nested set of subgenomic mRNAs (sgRNAs) that are produced via a discontinuous transcription mechanism (6, 30). Each of these sgRNAs has a short nontranslated leader sequence (64 nucleotides for IBV) derived from the 5′ end of the genome. Present within the leader sequence is a consensus sequence, which we have termed the transcription-associated sequence (TAS) (24). The TAS contains a conserved core motif, which in the case of IBV is CUUAACAA, which is also located in the genome, proximal to the start site for each sgRNA. For different coronaviruses, the core sequence varies and can be present more than once per TAS.

N protein, the virus RNA binding protein, is one of the most abundant viral proteins in an infected cell (31). Several functions have been postulated for the coronavirus N protein throughout the virus life cycle (31); primarily, it complexes with the genomic RNA to form a ribonucleocapsid structure (17) and associates with the M protein (19, 39) to form the viral core (48). While N protein is required in trans to rescue the full-length clone of IBV (8) and a porcine coronavirus transmissible gastroenteritis virus clone (82), it is not required for others (1, 71, 72). Certainly, in the case of the rescue of the full-length clone of severe acute respiratory syndrome coronavirus, the presence of N protein increases viral titers compared to rescue performed in the absence of N transcript (83), suggesting that N protein may be involved in the efficiency of replication but that it is not essential.

Based on amino acid sequence comparisons, three domains have been identified in the murine coronavirus, mouse hepatitis virus (MHV) N protein (46), of which the central domain (domain II) was identified as a potential RNA binding site (35, 40) capable of binding both coronavirus- and non-coronavirus-derived RNA sequences (35, 68). However, whether this binding occurs with equal or different affinity is uncertain (14, 35, 49). N protein has been shown to associate with several motifs on viral RNA, including the leader RNA sequence, with particular affinity for the core sequence of the TAS (2, 41), sequences at the 3′ end of the genomic RNA (84), and the packaging signal (37). How these sequences promote N binding is unknown.

Several coronavirus N proteins have been shown to be phosphorylated, including IBV, MHV, and transmissible gastroenteritis virus N proteins, although the precise sites were not identified (31). The role of phosphorylation in the virus life cycle is unknown, although the phosphorylation state of N protein has been predicted to play a role in determining the
The biotin moiety is denoted (B-), the authentic IBV gene 3 sequence is in uppercase, the random sequence is in lower case, and the position of the gene 3 TAS/scrambled/inactive TAS is in boldface type. The sequence that corresponds to predicted SL1 is single underlined, and that corresponding to predicted SL2 is double underlined.

### MATERIALS AND METHODS

**Biotinylated RNAmers.** Biotinylated RNA oligonucleotides used in this study were obtained from Invitrogen and purified by high-pressure liquid chromatography (HPLC). Their sequences are shown in Table 1 and schematically represented as follows.

Redenominated plasmids and viruses. To synthesize recombinant IBV N protein from *E. coli*, the IBV (strain Beaudette) N protein gene was cloned into pTriExIBVN as described previously (13). Vero (simian) cells were maintained in Dulbecco modified Eagle medium and left for an additional 20 h. Vero cells were infected with 1 ml of IBV Beaudette (multiplicity of infection of approximately 1) and incubated for 1 h at 37°C. The initial inoculum was replaced with 1 ml of media and incubated for a further 7 h postinfection.

Preparation of total protein extracts from Vero cells and Western blotting. Vero cells were washed with phosphate-buffered saline, detached by a cell scraper into 1 ml of phosphate-buffered saline, pelleted by centrifugation at 250 × g for 5 min before lysis by addition of 200 μl of cell lysis buffer (20 mM Tris-HCl [pH 7.5], 100 mM NaCl, 0.5 mM EDTA, 0.5% NP-40, and 40 μl of protease cocktail inhibitor [Roche]) for 10 min at 4°C. Samples were centrifuged at 10,000 × g for 5 min at 4°C, and supernatants were transferred into a new Eppendorf tube and stored at −80°C.

Preparation of N protein from *E. coli*, Sf9, and Vero cells. Expression and purification of His-tagged N protein from either *E. coli* or Sf9 cells has been previously described (12, 13). To obtain N protein from mammalian cells, Vero cells were transfected with pTriExBNV as described previously (13), and purification was identical to that described for N protein from Sf9 cells. Western blotting was performed by using the ECL detection kit (Amersham Pharmacia) according to the manufacturer's instructions. Briefly, each sample (3 μg of total protein as quantified by Bradford assay) was separated on a 10% NuPage Bis-Tris precast polyacrylamide gel (Invitrogen) in a running buffer. Protein was transferred onto a polyvinyldene difluoride membrane (Invitrogen) in Invitrogen transfer buffer for 1 h at room temperature. The membrane was blocked for 1 h in Tris-buffered saline (TBS) plus 0.05% Tween 20 and 5% milk. Primary rabbit anti-IBV polyclonal sera (gift from D. Cavanagh, IAH Compton) were diluted 1:10,000 in TBS plus 0.05% Tween 20 and 5% milk. The membrane was washed three times in TBS plus 0.05% Tween, and then the membrane was incubated with secondary goat anti-rabbit immunoglobulin G conjugated to horseradish peroxidase (diluted 1:1,000 in TBS plus 0.05% Tween) for 1 h at room temperature. The membrane was then washed three times, treated with ECL detection reagents (Amersham Pharmacia), and subjected to autoradiography.

**Mass spectroscopy.** Recombinant IBV N protein (from *E. coli* [pCI-Neo-N] or Sf9 [pTriEx1.1] cells) was dialyzed into digest buffer (100 mM ammonium bicarbonate, 1% urea [pH 8.0]). Samples were digested by the digest mixture of 75 μl of trypsin (2 μg of trypsin), 20 μl of 100 mM ammonium bicarbonate, and 5 μl of 0.1% trifluoroacetic acid. Resulting tryptic peptides were analyzed by online capillary HPLC-mass spectrometry (MS). Samples were preconcentrated and desalted by use of a self-packed protein trap, followed by separation by use of a 180-μm-inner-diameter capillary column, self-packed with...
Hichrom C18 reversed-phase sorbent (3.5-μm bead size, 150-Å pore size). Peptides were eluted from the column by an increasing gradient of solvent B (0.05% vol/vol trifluoroacetic acid in 5:95 water-acetonitrile), and solvent A was 0.05% vol/vol trifluoroacetic acid in 95:5 water-acetonitrile. The eluent was passed, via a U-Z View UV flow cell (LC Packings), to a Quattro II tandem quadrupole mass spectrometer (Micromass United Kingdom Ltd.). The mass spectrometer was equipped with a commercially available Z-spray source operated in continuous flow nanospray mode. Full-scan mass spectra were acquired in positive-ion mode from an m/z of 300 to 2,100 with a scan time of 4 s. The voltage applied to the extraction cone was ramped to improve detection of high-m/z ions. Recombinant IBV N protein expressed by Vero cells (N Vero) was digested with trypsin and analyzed by HPLC-MS or automated HPLC-MS/MS at Micromass United Kingdom Ltd. Peptides were separated on a reversed-phase capillary HPLC column (75-μm C18, Pepmap; LC Packings), and the eluent was passed directly to the Z-spray source of a Micromass Q-Tof Ultima API (Waters Corp.) mass spectrometer. The mass spectrometer was operated in data-dependent acquisition mode to generate peptide sequence information automatically, and theoretical phosphopeptide ions were added to the include list to ensure that these peptides were sequenced.

Runoff transcription and hybridization of CD-61 RNA to biotinylated oligo(dT). pCD-61 containing the cDNA for the 6.1-kb minigenome of Beaudette IBV was made linear by digestion with NotI. RNA with a 3’ poly(A) tail was in vitro synthesized from pCD-61 by using T7 RNA polymerase (Promega) as described previously (47). RNA (2.5 pmol) was denatured in 400 μl of 0.5 × SSC.

Chi-square test, 1.98.

RESULTS

We wanted to investigate the role of phosphorylation and viral RNA sequences in the binding of the coronavirus N protein to RNA by using surface plasmon resonance. Therefore, a source of both purified nonphosphorylated and phosphorylated N protein was required. Previous studies have successfully used a variety of sources of N protein to study RNA binding, including bacterially expressed N protein (41, 84), in vitro-transcribed and -translated N protein (35, 49) (which in both cases were presumably not phosphorylated), or N protein obtained from infected cell lysates (14) (and thus containing a mixture of nonphosphorylated and phosphorylated viral and cellular proteins). It was previously shown that N protein produced in Vero cells (the model mammalian cell line used to study IBV infection) has identical electrophoretic mobility to that produced in insect (SF9) cells, both of which had slower mobility than N protein produced in E. coli (12), suggesting that N protein synthesized in Vero and SF9 cells had undergone posttranslational modification. We note that Western blot analysis suggested that N protein produced in Vero cells (by transfecting cells with pTriExIBV [13], a plasmid which expressed N protein under a PolIII promoter) has identical mobility to N protein isolated from Vero cells at 8 h postinfection (i.e., the virus has undergone one infectious round) (Fig. 4).

While it was not possible to purify N protein from virions, by
using mass spectroscopy, we investigated the posttranslational modifications that occurred on N protein produced in Vero cells to N protein produced in Sf9 cells. If posttranslational modifications of N protein in Sf9 cells were the same as N protein synthesized in Vero cells, then we would use N protein produced by the former method as our source of phosphorylated protein for surface plasmon resonance, as larger amounts of protein can be obtained for analysis. N protein produced in and purified from *E. coli*, Sf9 cells, and Vero cells was analyzed by dynamic light scattering (data not shown), which indicated that the protein was monodisperse and had a hydrodynamic radius (whatever the source) of approximately 10 nm.

**IBV N protein contains internal disulfide bonds.** IBV N protein expressed in *E. coli*, Sf9 cells, and Vero cells was subjected to proteolytic digestion and analysis by capillary HPLC-MS. A representative HPLC chromatogram from analysis of peptides released by tryptic digestion of Npro*E. coli* is shown in Fig. 5. Many proteolytic peptides were identified, which covered a large amount of the IBV-N protein sequence; peaks are labeled with the residue numbers that the peptides span.

Comparison of peptide profiles before and after reduction with dithiothreitol allowed us to identify various peptides that contained disulfide bonds. Based on the masses of these peptides, we tentatively assigned disulfide bonds between residues Cys281 to Cys308 and Cys320 to Cys323. To confirm these assignments, we also desalted a portion of the peptide mixture by use of a ZipTip and subjected these peptides to tandem MS analysis by using collision activation. Figure 6 shows the tandem mass spectrum of the peptide believed to contain residues 318 to 331, with an internal disulfide bond between residues Cys320 and Cys323. The fragment ions are labeled according to the convention of Roepstorff and Fohlman (50), and this spectrum confirms the identity of the peptide. After reduction, the mass of this peptide increased by 2 Da, and this confirmed the presence of the disulfide bond. Likewise, we obtained MS/MS data that confirmed our assignment of the disulfide bond between Cys281 and Cys308 (data not shown). The presence of these two disulfide bonds was also confirmed in Npro*E. coli* by similar methods (data not shown). A range of peptides covering over 65% of the sequence of Npro*E. coli* was identified, but we found no
evidence for further posttranslational modifications in this protein.

NSf9 contains additional posttranslational modifications. Comparison of digests of N _E. coli_ with N _Sf9_ allowed us to investigate posttranslational modifications that are specific to N _Sf9_. Partial digestion of N _E. coli_ with endoproteinase Glu-C produced two N-terminal fragments corresponding to residues 1 to 182 and 1 to 220, which had measured masses close to their theoretical masses, implying that no modifications had occurred within this region (Fig. 7a). The corresponding polypeptides from N _Sf9_ had measured masses that were different from those predicted from the sequence. The measured mass of residues 1 to 182 was 19,574 Da, around 44 Da higher than the measured mass of N _E. coli_ protein residues 1 to 182. In addition, N _Sf9_ protein residues 1 to 220 were present in three different forms; the lowest-mass form had a measured mass that was, again, 44 Da higher than that of N _E. coli_ residues 1 to 220. The other species had measured masses that were a further 81 and 157 Da higher (Fig. 7b). These mass shifts occurred in the polypeptide spanning residues 1 to 220 but not residues 1 to 182, suggesting that the modifications were within residues 183 to 220.

![Graph](image1.png)

**FIG. 5.** Capillary HPLC-MS analysis of peptides released after tryptic digestion of N _E. coli_. Peptides were detected by both UV absorbance at 214 nm (upper trace) and mass spectrometric total ion current (TIC, lower trace). Peaks in the upper trace are labeled with the retention time of the peptides, and those in the lower trace are labeled according to the residue numbers of N _E. coli_ tryptic peptides that were identified. Peaks marked with asterisks correspond to trypsin autolysis products.

![Graph](image2.png)

**FIG. 6.** Tandem mass spectrum of a putative disulfide bond-containing peptide. The peptide covers residues Ile318 to Lys331 and was released by tryptic digestion of N _E. coli_. The presence of both diagnostic b and y series fragment ions confirm the identity of this peptide. The mass of the peptide was observed to increase by 2 Da after reduction of disulfide bonds with dithiothreitol, confirming the existence of the single disulfide bond within this peptide.

![Image](image3.png)
The modification of 44 Da within residues 1 to 182 was consistent with acetylation (addition of 42 Da), and a proteolytic peptide spanning residues 1 to 51 also carried this modification (measured difference, 42.6 Da) (data not shown). The measured mass differences occurring between residues 183 to 220 were consistent with the addition of two phosphate groups (phosphorylation results in a mass increase of 80 Da per group). Endoproteinase Glu-C digestion also generated C-terminal peptides with different masses between N\textsubscript{E. coli} and N\textsubscript{Sf9} proteins, suggesting additional phosphorylation sites within this domain (data not shown).

Residues in both the N- and C-terminal domains are phosphorylated in both N\textsubscript{Sf9} and N\textsubscript{Vero} proteins. To locate the sites of phosphorylation, N\textsubscript{Sf9} was digested with trypsin to yield smaller fragments; the peptide pool was desalted by use of a ZipTip and was analyzed by offline MS in negative-ion mode. To specifically detect phosphopeptides, a precursor ion scan was used that detected peptides fragmenting to yield a moiety of an m/z of 79 (PO\textsubscript{4}\textsuperscript{−}). The resulting spectrum is shown in Fig. 8, and peaks are labeled with putative residue numbers of the peptides, assigned solely from the peptide mass. From these data, it appears that there are two sites of phosphorylation between residues 186 to 198 and a further two between residues 367 to 394. A fresh aliquot of tryptic peptide mixture was analyzed in positive-ion mode, and the relevant phosphopeptides were subjected to collision activation experiments by MS/MS. The MS/MS spectrum of the doubly phosphorylated peptide with a mass of 3,460.4 Da from N\textsubscript{Sf9} is shown in Fig. 9a. Fragment ions were labeled according to the convention of Roepstorff and Fohlman (50). Neutral losses of 98 Da (H\textsubscript{2}PO\textsubscript{4}) from the parent ion, characteristic of phosphopeptides, was observed. In addition, structural information was obtained from sequence-specific fragment ions, which are shown more clearly in the magnified inset of Fig. 9a. By comparison with corresponding MS/MS spectra of singly and unphosphorylated peptides, the sites of phosphorylation were distinguished. The data showed that the peptide spans residues 367 to 394 and that the sites of phosphorylation are Thr\textsuperscript{378} and Ser\textsuperscript{379}. In the singly phosphorylated peptide, however, it is not clear which of these two sites is occupied.

MS/MS spectra were also obtained on putative phosphopeptides from the N-terminal region of N\textsubscript{Sf9} (data not shown), and these confirmed that the sites of phosphorylation are Ser\textsuperscript{190} and Ser\textsuperscript{192}. The MS/MS spectrum of the nonphosphorylated peptide confirmed the identity of the peptide, whereas that of the singly phosphorylated peptide demonstrated that Ser\textsuperscript{192} was occupied in preference to Ser\textsuperscript{190}.

To confirm that these phosphorylation sites were present in N protein expressed by mammalian cells, the protein was expressed in Vero cells (N\textsubscript{Vero}), digested with trypsin, and analyzed by HPLC-MS. Since the amount of protein obtained from these cells was low, this analysis was performed by use of a more-sensitive mass spectrometer, a Q-ToF instrument. The tryptic digest of N\textsubscript{Vero} was similar to that of N\textsubscript{Sf9}, and putative phosphopeptides were observed with the same masses as measured for N\textsubscript{Sf9}. Operating in data-dependent acquisition mode allowed peptides to be automatically subjected to MS/MS analysis as they eluted from the column, and this included putative phosphopeptides. The MS/MS spectrum of the singly phosphorylated peptide spanning residues 188 to 198 from N\textsubscript{Vero} is shown in Fig. 9b. It is identical to that obtained from N\textsubscript{Sf9} (data not shown) and confirms that the initial site of phosphorylation in the N-terminal region is Ser\textsuperscript{192}. We also obtained MS/MS spectra for the C-terminal phosphorylation sites. Our data indicated that the same phosphorylation sites were occupied in N\textsubscript{Vero} as were found in N\textsubscript{Sf9}, establishing that N\textsubscript{Sf9} is a relevant model for phosphorylated N protein and thus could be used for kinetic analysis. N protein produced in E. coli is subsequently referred to as N\textsubscript{Nonphospho} and N protein produced in Sf9 cells is referred to as N\textsubscript{phospho}.

Comparison of the affinity of binding of nonphosphorylated and phosphorylated forms of N protein with viral RNA by using surface plasmon resonance. We compared the binding of N\textsubscript{Nonphospho} protein and N\textsubscript{Phospho} protein with two models of the IBV genome. The first was RNA synthesized in vitro transcription from pCD-61. The second was a synthetic biotinylated RNA, RNAmer 3LeaderTAS, which was identical to the 5′ end of IBV mRNA 3 up to, and including, the translation initiation codon for gene 3a. CD-61 RNA was generated by
runoff transcription from pCD-61 and hybridized to oligo(dT), which was immobilized on a streptavidin flow cell.

Various concentrations of either N nonphos or N phos proteins were passed over immobilized CD-61 RNA. The resultant sensorgrams are shown in Fig. 10, and kinetic analysis is shown in Table 3. The data suggested that there was no significant difference in the binding of N nonphos protein ($K_d$, 8.89 ± 0.08 nM) to CD-61 than N phos protein ($K_d$, 16.9 ± 0.53 nM), which indicated that both forms of N protein associated with viral RNA with high affinity. The preparation of the CD-61–oligo(dT) complex may also have contained free oligo(dT), which was available to bind to the streptavidin flow cell. However, we found that N protein did not bind to immobilized oligo(dT) (data not shown), suggesting that any binding characteristics of the CD-61–oligo(dT) complex were due to interactions with CD-61 RNA only.

Biotinylated RNAmer 3LeaderTAS was immobilized directly onto the streptavidin flow cell, 12.5 nM N nonphos protein or N phos protein was passed over, and the binding affinity was determined. The sensorgrams for 3LeaderTAS with N phos and N nonphos proteins are shown in Fig. 11 and 12, respectively. The kinetic analysis of the binding experiments is shown in Table 4. On first inspection, the data indicated that N nonphos protein ($K_d$, 0.657 nM) had a higher affinity for 3LeaderTAS than N phos protein ($K_d$, 2.82 nM). However, we found that the variation in binding affinities between replicate experiments with RNAmers was approximately 1.5 nM (data not shown), suggesting that any binding characteristics of the CD-61–oligo(dT) complex were due to interactions with CD-61 RNA only.

Abolition of the core sequence did not appear to significantly affect the affinity of binding of Nphos to the IBV gene 3 leader sequence. However, the addition of the core site to Random90 is approximately 170 times lower than that of N nonphos protein. The dissociation rates for both proteins are approximately the same. These data indicate that phosphorylation of N protein decreases the affinity for random RNA. A side-by-side comparison of the binding of both species of N protein with 3LeaderTAS and Random90 is also shown in Fig. 12.

Core sequence determines association rate. We investigated the effect of the core sequence on RNA binding by using two different approaches: by scrambling the core sequence from gene 3 (RNAmer 3LeaderSAT) and by replacing eight nucleotides of the Random90 sequence with the gene 3 core site (RNAmer Random90TAS) in the same location as the viral RNA, i.e., at nucleotide 57 of the leader sequence. The mutations introduced into the gene 3 core sequences in RNAmer 3LeaderSAT were the same mutations that abolished transcription in an IBV minireplicon (65) and were thus biologically relevant. Both biotinylated RNAmers were immobilized to the streptavidin flow cell, and then 12.5 nM N phos protein was passed over these ligands for 360 s. The sensorgrams for RNAmer Random90 are shown in Fig. 11 and 12. The kinetic analysis of the binding experiments is shown in Table 4. The binding affinity of Nphos protein to RNAmer Random90 was 810 nM compared to 3.24 nM for N nonphos protein, a 250-fold difference. This was probably because the association rate of N phos protein to RNAmer Random90 is approximately 170 times lower than that of N nonphos protein. The dissociation rates for both proteins are approximately the same. These data indicate that phosphorylation of N protein decreases the affinity for random RNA.

Phosphorylation decreases the affinity of N protein for random RNA. As a model for nonviral RNA, we synthesized a biotinylated RNAmer (Random90) of identical length to RNAmer 3LeaderTAS that was based on the E. coli sequence, but the GC content was reduced to reflect a GC ratio (28%) similar to that of the leader RNA. The biotinylated RNAmer was immobilized to the streptavidin flow cell, and then 12.5 nM concentrations of both forms of N protein were injected for 360 s. The sensorgrams for RNAmer Random90 are shown in Fig. 11 and 12. The kinetic analysis of the binding experiments is shown in Table 4. The binding affinity of N phos protein to RNAmer Random90 was 810 nM compared to 3.24 nM for N nonphos protein, a 250-fold difference. This was probably because the association rate of N phos protein to RNAmer Random90 is approximately 170 times lower than that of N nonphos protein. The dissociation rates for both proteins are approximately the same. These data indicate that phosphorylation of N protein decreases the affinity for random RNA.

A side-by-side comparison of the binding of both species of N protein with 3LeaderTAS and Random90 is also shown in Fig. 12.
increased the affinity of binding of N\textsubscript{phos} protein to RNA approximately 240 times, mainly due to the increased association rate, indicating that the core site affected the association rate between N\textsubscript{phos} protein and RNA but not the dissociation rate. The same trend was observed for the binding of N\textsubscript{nonphos} protein to these RNAmers (Table 4; Fig. 11), and the difference in binding affinity by N\textsubscript{nonphos} protein and the different RNAmers was less than that for the N\textsubscript{phos} protein.

Multiple N protein binding sites are present in leader sequence. The above data indicated that, although the TAS acted to promote high-affinity binding of N protein on a nonviral RNA, when the site was mutated in the leader sequence, there was no significant difference to binding, suggesting that other binding sites may be present. Analysis of the structure of the IBV leader sequence indicated that two predicted stem-loops were formed and that the sequences corresponding to these predicted structures were conserved in different strains (66). Where nucleotide differences occurred between strains, a corresponding covariant mutation was present to conserve the appropriate predicted stem-loop structure (66). Predicted stem-loop one (SL1) is formed between nucleotides 7 and 30, and predicted stem-loop two (SL2) is formed between nucleotides 34 and 48. Although a third stem-loop is formed when predicting the structure of the leader sequence, this feature is not present when the analysis is extended in the 3' direction (P. Britton, personal communication). Therefore, we investigated the role of the two conserved predicted stem-loop regions upstream of the core element in binding phosphorylated N protein. Appropriate regions of the leader sequence were replaced with the corresponding nucleotides from the random nonviral...
Role of SL1 in N protein binding. SL2 and sequences downstream of the TAS were replaced with random RNA, forming RNAmer SL1TASrand, so the RNA contained only SL1 and a TAS. Nphos protein bound to this RNA with higher affinity (K_d, 0.63) than to the leader RNA (Table 4; Fig. 11). Unfortunately, an RNAmer containing SL1 only proved difficult to synthesize, and thus, we were unable to determine the binding affinity of Nphos protein to SL1. However, the binding affinity of Nphos protein to SL1TASrand is greater than to RandomTAS, suggesting that SL1 can promote high-affinity binding.

Binding of Nphos protein to antileader RNA. In coronavirus-infected cells, negative-sense copies of sgRNAs are present and contain antivirals (60). These negative-strand RNAs can act as templates for the synthesis of positive-strand sgRNAs (24, 54–57, 59). We investigated the binding of Nphos protein to antileader RNA. This RNAmer was the exact anticopy of 3LeaderTAS, except that it was one nucleotide shorter because the synthesis process could not terminate with a U (Invitrogen). The kinetic analysis (Table 4; Fig. 11) indicated that Nphos protein formed a high-affinity association with antileader RNA (2.17 nM).

DISCUSSION

The RNA binding kinetics of the coronavirus nucleoprotein to RNA and relevant binding motif(s) and the role of phosphorylation in this process has not previously been determined. To model this, we made use of IBV N protein purified from either E. coli or Sf9 cells to generate nonphosphorylated and phosphorylated proteins, respectively, which we have used to study interactions with nucleolin (13). Mass spectroscopy confirmed that N protein purified from E. coli was nonphosphorylated, whereas N protein purified from Sf9 cells was phosphorylated. These phosphorylation sites were identical to the phosphorylation sites found on N protein expressed in Vero cells, which is the mammalian cell line model for IBV. The data suggested that IBV N protein could be phosphorylated at two clusters, amino acid residues Ser190 and Ser192 and Thr378 and Ser379, which are proximal to RNA binding domains. The majority of species was either mono- or biphosphorylated. These sites are predicted casein kinase II (CKII)

phosphorylation sites (32). Additional acidic amino acids in positions +1, +2, +4, and +5 have been reported to increase the phosphorylation rate at CKII sites, whereas a basic residue N-terminal of the site will decrease the phosphorylation rate. In the case of Ser190, there are acidic amino acids in the +1 (Asp191), +4 (Asp193), and +5 (Asp194) positions (Fig. 13). However, there are two basic residues N-terminal of this site (Arg188 and Arg189), which may account for the observation that Ser192 was occupied in preference to Ser190. In the case of Ser192, there are acidic amino acids in the +2 (Asp193) and +3 (Asp194) positions (Fig. 13). For the C-terminal phosphorylation sites, Thr378 has preferential acidic amino acids in the +2 (Asp380) and +4 positions (Asp382) and Ser379 has preferential acidic amino acids in the +1 (Asp380) and +2 (Asp381) positions (Fig. 13). CKII is present in the mitochondria and cytoplasm, but predominately in the nucleus, and several nuclear proteins serve as substrates, for example, p53, RNA polymerases I and II, and the nucleolar proteins B23 and C23 (32). Phosphorylation by CKII alters the nucleic acid or catalytic activity of some of these substrates. Coronavirus N proteins have both a cytoplasmic and nuclear/nucleolar distribution (25, 42, 81), as do other N proteins of the Nidovirales (31, 52, 74). Therefore, it is interesting to speculate that coronavirus N proteins can be posttranslationally modified by nuclear proteins (e.g., phosphorylation by CKII), suggesting nuclear involvement in positive-strand RNA virus replication (22, 23, 77). CKII has also been shown to be involved in the phosphorylation and transcriptional activity of a number

of viral proteins, including vesicular stomatitis virus P protein (3).

HPLC analysis of tryptic phosphopeptides revealed that phosphorylation of MHV N protein occurred at only two or three sites (79), which Laude and Masters (31) suggested was relatively small, given that MHV N protein had some 30 to 40 potential target residues for phosphorylation. Sequence analysis indicated that IBV had at least 10 potential residues for phosphorylation (53); however, our mass spectroscopy results for IBV N protein would support the hypothesis that relatively few potential sites of phosphorylation in the coronavirus N proteins are phosphorylated.

Although our principal aim with mass spectroscopy was to investigate the phosphorylation status of N protein, analysis revealed several other potential modifications. We found that the N-terminal region of N protein may be acetylated. Acetylation in the N-terminal region of both cellular and viral proteins is a common posttranslational modification, e.g., the phosphoprotein (P) of some paramyxoviruses (62). Although acetylation of proteins has a number of different functions, it is also involved in transcriptional regulation, e.g., acetylation of human immunodeficiency virus Tat protein (43) and CREB-mediated gene expression (33). Acetylation of the coronavirus N protein could therefore play a role in the transcriptional regulatory activity the protein may display. N protein from the three different sources had identical disulfide bridges, formed between residues Cys281 and Cys308 and Cys320 and Cys323. Analysis of N protein by sodium dodecyl sulfate-polyacrylamide gel electrophoresis analysis under native conditions indicated that the predominant species in solution were both monomeric and multimeric (but not dimeric), whereas under reducing conditions, N protein was present as a monomer only (12). Although these bridges may have formed during the extraction and purification of the protein, normally when this occurs, disulfide bridge formation occurs sequentially, and therefore, we would have predicted that disulfide bridges would form between Cys228 and Cys281 and Cys308 and Cys320. However, we did not observe this. Although N protein is cytosolic, non-endoplasmic reticulum-based redox pathways can contribute to disulfide bridge formation (61). Disulfide bridge formation may therefore be important in the correct folding of N protein. However, it should be noted that the severe acute respiratory syndrome coronavirus N protein does not contain any cysteine residues and therefore would not contain disulfide bridges (34).

Surface plasmon resonance (Biacore) has not previously been applied to the study of the interaction of coronavirus N protein with coronavirus RNA. Therefore, we used this technique to investigate the interaction of nonphosphorylated and phosphorylated IBV N protein with a variety of viral and nonviral target RNAs. In the case of the biotinylated RNAsmers, we were able to examine the interaction of N protein with target RNAs at near physiological temperature (37°C). We examined the binding of nonphosphorylated and phosphorylated N protein on both the gene 3 leader sequence and CD-61. There was no significant difference in the binding of nonphosphorylated and phosphorylated N protein to leader RNA or a defective interfering RNA (DI-RNA). Our results are in contrast to those of Cologna et al. (14), who found that the bovine coronavirus (BCoV) N protein bound more efficiently to a BCoV minireplicon than to the BCoV leader sequence. This discrepancy may be due to the differences between filter binding assays used by Cologna et al. (14) and surface plasmon resonance (45) used in our study, or it may be an intrinsic property of the different coronavirus N proteins. However, our results suggested that phosphorylated N protein had 264 times...
greater affinity for the leader sequence than a nonviral RNA. N protein failed to bind to an oligomer with 25 T residues, indicating that sequence context may be important for nucleotide binding. The differences in the amount of N binding to RNA, the source of N protein, and the kinetics of this interaction may account for why previous studies could not resolve whether N bound either specifically to viral RNA or bound with equal affinity to both viral and nonviral RNA.

Nelson et al. (41) measured the binding affinity of MHV N protein (isolated from E. coli and therefore nonphosphorylated).

*Where two values are given for a target RNA, the result for phosphorylated N protein is given above the result for nonphosphorylated N protein.

**FIG. 13.** Amino acid sequence of the IBV Beaudette strain N protein (5) showing the sites of phosphorylation and disulfide bridge formation.
ed) to the MHV leader sequence and obtained a $K_D$ of 14 nM. Although the binding affinity of IBV N$_{\text{nonphos}}$ protein to the IBV leader ($K_D$, 0.66 nM) is greater than that of MHV N protein to MHV leader, this may be a reflection of the differences in recombinant N protein preparation (His tag in the case of IBV N protein versus glutathione S-transferase fusion for MHV N protein) and kinetic measurement (surface plasmon resonance versus filter binding assay). With that said, the binding affinity of MHV N protein to MHV leader (41) and IBV N protein to IBV leader is very strong and thus probably reflects a general pattern for coronaviruses. Consideration should be given to the fact that N protein in virions and the infected cell is exclusively phosphorylated and is probably not nonphosphorylated (31). A phosphoamino acid analysis of the arterivirus (a member of the Nidovirales) porcine reproductive and respiratory syndrome virus nucleocapsid protein revealed that this protein was also exclusively phosphorylated, and no nonphosphorylated species were found (80). Therefore, care should be taken when interpreting the results obtained with nonphosphorylated N protein and drawing biologically relevant conclusions, as this form of N protein is probably not present in virus-infected cells. We favor the hypothesis that the role of phosphorylation is to decrease the affinity of N protein for random RNA so that N protein associates with viral RNA in preference to cellular RNA.

Comparison of the binding affinity between IBV N protein and RNA and other RNA binding proteins also revealed that N protein had high-affinity binding. Using surface plasmon resonance, Park et al. (45) determined the binding affinity for human neuron-specific RNA binding (HuD) protein with AU-rich target biotinylated RNAs was approximately 0.7 nM. In this experiment, recombinant HuD protein was C-terminally His tagged and purified from E. coli and presumably nonphosphorylated. The binding affinity of IBV N$_{\text{nonphos}}$ and N$_{\text{phos}}$ protein to leader RNA is similar.

The principal function of N protein in terms of the infectious cycle of the virus can perhaps be viewed as binding to viral RNA to form the ribonucleocapsid structure, part of the core particle. In a number of viruses, viral capsids can form in the absence of RNA and instead can be replaced with either cellular RNAs or suitable polyanions; this has been perhaps best characterized in the encapsidation and assembly of nodavirus particles (29, 58, 73). The high affinity of phosphorylated N protein for viral RNA over nonviral RNA together with appropriate packaging signals (16, 18, 20, 37) may explain why virions are composed of viral RNA (48).

Using the phosphorylated form of N protein, we found that the IBV gene 3 core sequence contributed to the kinetics of RNA binding. Introducing a core sequence into nonviral RNA (Random90) increased N binding, with the major change being in the association rate. Scrambling the core sequence in the context of the leader RNA resulted in only a small decrease in binding affinity, suggesting that the core sequence was not the only N protein-binding site present on leader RNA. Stirrups et al. (66) described two conserved predicted stem-loops that were present upstream of the core sequence in the leader sequence. By replacing these sequences with random RNA (from Random90), that did not promote high-affinity binding, we showed that the sequences that form predicted SL1 and predicted SL2 both contributed to high-affinity binding of phosphorylated N protein to leader RNA. However, it should be noted that optimum RNA ligand binding sequences are not necessarily the same as those found in vivo (78). The high-affinity binding of N protein to the stem-loop structures may suggest that N protein could be a general double-stranded RNA binding protein. However, structural analysis of RNAmers Random90 indicated that this molecule formed stem-loop structures (data not shown), and in the case of the phosphorylated N protein, we observed low-affinity binding with this target compared to viral RNA, suggesting that, in general, N protein did not specifically recognize double-stranded RNA.

Such stem-loop structures have also been identified in the 5' end of several other coronaviruses, including BCoV DI-RNA (10, 11) and MHV (75), and these sites may therefore also act as high-affinity sites for N protein. However, with that said, in their kinetic analysis, Stohlman et al. (68) located only one high-affinity binding site on the MHV leader RNA that bound MHV N protein, and this site encompassed the MHV core element. But discrepancies between our findings with IBV leader sequence and IBV N protein and the MHV leader sequence and MHV N protein, may be a reflection of the inherent properties of the molecules themselves or of the different kinetic analysis used.

The high-affinity association of phosphorylated N protein with the leader sequence and TAS may have implications for viral translation and possibly replication. If coronavirus mRNAs are translated in a cap-dependent manner, in that they initiate translation at the 5' end of the leader sequence, then the ribosome may be in conflict with the N protein when it scans along the leader sequence for the translation start codon. However, Tahara et al. (70) have speculated that N protein enhances the translation of MHV mRNAs. In this case, one may hypothesize that by binding to the leader RNA, N protein may reduce the secondary structure to increase the efficiency of translation.

N protein may also bind, with high affinity, to the TAS elements located along the coronavirus genome, and one may therefore speculate that this interaction is involved in the efficiency of transcription of (minus) sgRNAs. Also, N protein may bind to sites that are very similar in sequence to the core element (44) to facilitate transcription at these sites. Although the caveat is that N protein is not required to rescue all of the full-length coronavirus clones so far described, the presence of N protein does increase the rescue efficiency. An alternative is that the TAS sites act as nucleation sites for N protein to facilitate the encapsidation of virus RNAs. Such binding sites may act separately from the packaging signal that promotes a specific interaction with the N protein and the genomic RNA (18, 37) and presumably is required for the efficient packaging of the genomic RNA, but not sgRNAs, into core particles. MHV genomic RNA has been reported to be incorporated into the virion in the absence of N protein (38).

In their review, Laude and Masters (31) described how several workers speculated that phosphorylation of N protein may determine its binding affinity with RNA. Our data indicated that phosphorylation of N protein decreased the affinity of N protein for random RNA. Two possible mechanisms may account for this regulation. Phosphorylation of N protein may alter its conformation and thus affect the RNA binding site(s). Stohlman et al. (69) suggested that phosphorylation of MHV N
protein could lead to substantial conformational changes in protein structure, and phosphorylation of human immunodeficiency virus type 1 Rev protein was shown to alter its conformation and RNA binding properties (21). Our mass spectroscopic data would support the hypothesis of Stohlman et al. (69), that phosphorylation occurs proximal to RNA binding domains. Alternatively, phosphorylation of N protein could add negative charge to the RNA binding domains and thus reduce electrostatic interaction with target RNA. A similar mechanism has been proposed to regulate binding of potato virus A coat protein to RNA (26). While this would explain the overall slight binding difference between N_nonphos and N_phos with viral RNA, such an interaction probably does not account for the large difference in binding between N_phos protein and random RNA. Although the role of the conserved core sequence in N protein binding has been known for sometime, the mechanism by which this is achieved was not. Our kinetic study would suggest that the core sequence determines the specificity of IBV N protein binding with viral RNA by increasing the association rate. However, this is not the only site within the IBV leader that promotes high-affinity binding with N protein, and the possibly exists that these structures act in concert to promote optimal binding.

ACKNOWLEDGMENTS

This work was supported by a BBBSRC project grant (45/S12883) to J.A.H.

We thank Paul Britton for help in design of the leader RNAmers and Dave Cavanagh (IAH Compton) for the generous donation of pCD-61.
