Received 23 January 2006/Accepted 10 April 2006

Coronaviruses cause a variety of respiratory and enteric diseases in animals and humans including severe acute respiratory syndrome. In these enveloped viruses, the filamentous nucleocapsid is formed by the association of nucleocapsid (N) protein with single-stranded viral RNA. The N protein is a highly immunogenic phosphoprotein also implicated in viral genome replication and in modulating cell signaling pathways. We describe the structure of the two proteolytically resistant domains of the N protein from infectious bronchitis virus (IBV), a prototype coronavirus. These domains are located at its N- and C-terminal ends (NTD and CTD, respectively). The NTD of the IBV Gray strain at 1.3-Å resolution exhibits a U-shaped structure, with two arms rich in basic residues, providing a module for specific interaction with RNA. The CTD forms a tightly intertwined dimer with an intermolecular four-stranded central β-sheet platform flanked by α helices, indicating that the basic building block for coronavirus nucleocapsid formation is a dimeric assembly of N protein. The variety of quaternary arrangements of the NTD and CTD revealed by the analysis of the different crystal forms delineates possible interfaces that could be used for the formation of a flexible filamentous ribonucleocapsid. The striking similarity between the dimeric structure of CTD and the nucleocapsid-forming domain of a distantly related arterivirus indicates a conserved mechanism of nucleocapsid formation for these two viral families.

Coronaviridae is a family of viruses which are the causative agents of human upper respiratory infections including common colds, as well as severe illnesses such as severe acute respiratory syndrome (SARS). Avian infectious bronchitis virus (IBV) is a major source of mortality in chickens worldwide and has a significant impact on the poultry industry. Other coronaviruses affect domestic animals and are of veterinary significance. Coronaviruses are enveloped viruses with a diameter ranging from 80 to 160 nm. Their viral genome consists of positive-sense single-stranded (ss) RNA of approximately 30 kb (36). The genomic RNA encodes a 3′ c terminal set of four or more subgenomic mRNAs with a common leader sequence at their 5′ ends. These subgenomic RNA segments encode various structural and nonstructural viral proteins that are required to produce progeny virions. The viral particle consists of a nucleocapsid or core structure surrounded by a lipid envelope in which the membrane glycoprotein (M) and another small transmembrane protein (E) are embedded. A series of protrusions composed of glycoproteins (S) anchored in the lipid envelope extend radially, forming up to 20-nm-long spikes which give the roughly spherical viral particles a crown (corona) appearance.

During the virus life cycle, multiple copies of the nucleocapsid phosphoprotein (N) interact intimately with genomic and subgenomic RNA molecules (1, 28) and together with M, the most abundant envelope protein, participate in genome condensation and packaging. The N and M proteins interact via their C termini, leading to specific genome encapsidation in the budding viral particle (19). Electron microscopic studies of detergent-permeabilized transmissible gastroenteritis virus capsids revealed that the internal ribonucleocapsid is a flexible filamentous structure with a diameter of approximately ∼10 to 15 nm and up to several hundred nanometers in length (33, 34). The highly basic N protein has a molecular mass ranging between 45 and 60 kDa in the various groups of coronaviruses and, along with its coding RNA, is synthesized in large amounts during infection (20, 37). The N protein is able to bind ssRNA nonspecifically but displays an increased affinity for viral genomic RNA (9). Packaging signals have been identified at the 5′ and 3′ termini of the genome for several coronaviruses, but not unambiguously for the IBV genome. Biochemical studies of murine hepatitis virus (MHV), IBV, and SARS coronavirus (SARS-CoV) have mapped the RNA binding function to a segment of 55 residues located at the N-terminal half of the N protein and the dimerization function to its C-terminal half (14, 29, 45). In addition to its structural role, the N protein is also implicated in other processes during infection including mRNA transcription, replication, and host cell modulation (16, 20, 25, 35, 39, 41, 44). The N protein is
also an important diagnostic marker for coronavirus disease and a major immunogen that can prime protective immune responses (23).

The recombinant N protein of coronavirus expressed in Escherichia coli is highly susceptible to proteolysis, making structural analysis of the full-length protein difficult. To date, there is only limited information on the structure of the ribonucleocapsid protein, including a nuclear magnetic resonance (NMR) analysis of the N-terminal domain of the SARS-CoV N protein (18) and our crystallographic study of the N-terminal domain of the IBV N protein (Beaudette strain) at 1.85-Å resolution (14). As yet, there is no X-ray crystallographic structure analysis of the C-terminal dimerization domain of a coronavirus N protein. In this paper, we present a structural analysis, at high resolution, of the two proteolytically stable domains of the IBV N proteins located at the N- and C-terminal ends, called NTD and CTD, respectively. The NTD structure of IBV (Gray strain), determined to a 1.3-Å resolution, is similar to the previously published Beaudette strain (12) but makes strikingly different quaternary associations. We describe the first crystal structure of the CTD dimerization domain of the coronavirus N protein at a resolution of 2.2 Å. Our X-ray crystallographic analysis of the NTD and CTD provides insight into the way these modules might interact with RNA and with the M protein. The various crystal forms also delineate a number of alternative protein surfaces that are likely to be used for the formation of a flexible filamentous ribonucleocapsid.

**MATERIALS AND METHODS**

Purification of full-length nucleocapsid protein and limited proteolysis. The full-length N protein was expressed as described previously (47). The protein was further purified by heparin affinity chromatography, concentrated to 1 to 2 mg/ml and checked for homogeneity using dynamic light scattering (DynaPro) and negative-stain electron microscopy. Limited proteolytic cleavage of the full-length N protein (1 to 2 mg/ml) was carried out with 2% (weight trypsin/weight protein) sequencing-grade trypsin (Roche) to identify stable domains. The identity of the amino termini of the proteolytic product(s) was determined by N-terminal amino acid sequencing and blotting onto a polyvinylidene fluoride membrane (PVDF-Immobilon-PSQ; Millipore). For construct optimization the identities of the carboxy-terminal amino acids were estimated based on secondary structure prediction and mass spectroscopic characterization of the proteolyzed protein.

Cloning, expression, purification, and crystallization of the tryptic fragments of N protein. The NTD and CTD proteins from two strains were employed in this study, namely, IBV Gray (CTD1, CTD2, and NTD1) and IBV Beaudette (CTD3) (Fig. 3). The proteins were cloned and expressed as glutathione S-transferase fusion proteins using the pET41 Etk-LIC vector (Novagen) or, for the Beaudette strain, as detailed previously (14) The expressed protein was purified using a glutathione S-Sepharose (Pharmacia) affinity column, followed by on-bead cleavage with enterokinase (EK-Max, Invitrogen). The cleavage reaction was performed by suspending 1 ml of beads in 40 ml of cleavage buffer (250 mM NaCl, 50 mM Tris-HCl [pH 8.0]) with 10 units of protease. Following proteolysis, the diluted supernatant was further purified by gel filtration chromatography on a Superdex 75 16/60 column (Pharmacia). The purified N- and C-terminal domains were concentrated to 5 to 8 mg/ml for crystallization.

**Data collection and phasing.** Diffraction data were collected at various synchrotron beam lines as indicated in Table 1. For each crystal, images were collected using an oscillation angle of 1° and integrated and scaled with XDS (36) using an oscillation angle of 1° and integrated and scaled with XDS (36). The Patterson function was determined using multilrengeal data collection and refinement.

anomalous dispersion data sets collected at two different wavelengths (Se peak, 0.9734 Å; Se inflection, 0.9748 Å). Positions of the four Se atoms were located using the SnB program (43) and refined using SHARP (overall figure of merit of 0.65) (2). An electron density map was calculated following density modification using CCP4 (8). An initial model was built using ARP/WARP (21) followed by manual model building using Coot (13). A few cycles of simulated annealing were performed with CNS (3) followed by model refinement using REFMAC5 (32). The structures of CTDs in the two other crystal forms (CTD2 and CTD3) were solved using MR procedures as implemented in PHASER (23). Model bias in both NTD and CTD structures was reduced by using the prime-and-switch technique implemented in SOLVE/RESOLVE (42). During the course of model building and refinement, the stereochemistry of the structures was checked by PROCHECK (22). The final statistics are provided in Table 2. Surface electrostatic potentials were calculated using DELPHI (30). All figures were generated using PyMOL (10) and ESPript (15).

### RESULTS

Identification of two stable independent domains of IBV N by limited proteolysis. Since the full-length recombinant protein aggregated and was degraded under a variety of experimental conditions, we sought to identify stable domains that were resistant to mild proteolysis. We used limiting amounts of trypsin and V8 protease. The digestion pattern with the V8 protease was not very distinct, yielding several diffuse bands.

<sup>a</sup> Rfactor = Σ||F<sub>obs</sub> - F<sub>calc</sub>||ΣF<sub>obs</sub>

<sup>b</sup> Rfree was calculated with 10% of reflections excluded from the whole refinement procedure.

Protein structure accession numbers. The coordinates for the molecules were deposited into the PDB with accession numbers 2GE7 (CTD1), 2GE8 (CTD2), 2CA1 (CTD3), and 2GEC (NTD1).
The full-length protein, however, could be cleaved into a “single” stable ~17-kDa band within 15 min of trypsinization. N-terminal sequencing allowed the identification of four tryptic fragments with two major cleavage sites at residues 19 and 219 and two secondary cleavage sites at residues 27 and 226 (Fig. 1A).

New constructs corresponding to these proteolytically resistant domains termed NTD (residues 19 to 162) and CTD (residues 219 to 349) were cloned, expressed, and purified. The NTD was monomeric at moderate protein concentrations, whereas the CTD was a dimer even at very low concentrations, as assayed by gel filtration chromatography (12). The NTD and CTD proteins tended to aggregate during the purification procedure and thus purified at very low concentrations and concentrated only prior to crystallization.

NTD and CTD crystallized in multiple crystal forms. The recently reported structure of NTD at 1.85-Å resolution corresponds to the Beaudette strain of IBV. We used the IBV Gray strain which crystallized in a different crystal form and diffracts to 1.3-Å resolution (Table 1, crystal form NTD1). The CTD yielded crystals with needle, rod, flat sheet, or hexagonal shapes under various conditions (Table 1, crystal forms CTD1, CTD2, and CTD3). Rod-shaped CTD1 crystals of Se-Met substituted protein diffracting to 2.0 Å were used for structure determination. The structures of CTD in the other crystal forms (CTD2 at 2.2-Å and CTD3 at 2.6-Å resolution) were determined subsequently by molecular replacement. These various crystal forms exhibit different packing arrangements, a number of which could mimic the intermolecular interactions that trigger the formation of the coronavirus nucleocapsid.

High-resolution structure of NTD. With the exception of five additional residues discernible at its N terminus, the present structure of NTD of IBV Gray strain is quite similar to the structure of the NTD of IBV Beaudette strain (Fig. 1C) (14). Briefly, the NTD monomer features a relatively acidic globular core of twisted antiparallel β-sheet surrounded by several loop regions. Prominent among the loop regions are two long segments corresponding to the N-terminal 12 amino acids (residues 22 to 34) and an internal arm spanning residues 74 to 86. These loops protrude from the globular core resulting in a “U”-shaped monomer (Fig. 1B).

A dimer of NTD subunits is present in the crystallographic asymmetric unit: two interlocking NTD monomers are arranged in a head-to-tail fashion with the basic arms of one monomer interacting with the acidic base of the other monomer (Fig. 1B). The main structural variation between the two NTD monomers related by noncrystallographic symmetry is that in one monomer, one of the arms of the “U” (internal arm) is disordered. The buried surface area of 2,150 Å² between the two NTD monomers indicates a rather strong interaction. This is in contrast with the previous structure of
approximately 5,000 Å² in their interaction. The distribution of secondary structure elements along the CTD amino acid sequence and the topology of the CTD dimer are shown in Fig. 3. The CTD dimer has a rectangular shape delimited by edges formed by the C-terminal α helices α3 (Fig. 2) with approximate dimensions of 40 Å × 40 Å × 20 Å. It features a concave floor of ~400-Å² area consisting of an antiparallel β sheet (β1-β2-β3-β4-β5) contributed by monomers A and B, respectively, surrounded by several α helices and one short 3 10 helix (Fig. 2). Helices α3 and α4 are connected by a loop and, together with their dimeric partners, form a groove which arches inward over this floor constituting the other mostly basic face of the CTD dimer. Recent biochemical and mass spectrometric studies on the IBV N protein (Beaudette strain) have suggested the possibility of disulfide bridges in the CTD (5). However, no intramolecular disulfide bridge is seen in the CTD dimer of either strain of IBV reported here. The present structure of the CTD is consistent with previous observations that the CTD is a dimer in solution, with several biochemical studies which map the dimerization domain of the full-length protein to its C-terminal domain (40, 45).

Multiple packing modes of CTD dimers. The CTD dimer is involved in various intermolecular interactions in the three crystal forms reported here. The presence of one dimer (CTD1) and three dimers (CTD2 and CTD3) and four dimers in the asymmetric unit of the CTD2 crystal form (Tables 1 and 2) permits an analysis of dimer-dimer interactions in various conditions of precipitant and pH. We focused on interactions with a buried surface area larger than 1,000 Å². Such an analysis could help in the identification of molecular surfaces that are used to assemble the nucleocapsid.

CTD1 dimers (pH, 4.5) which are related by the crystallographic 2, screw axis display three kinds of intermolecular contacts. One interaction (burying ~1,100 Å²) brings two dimers in a tail-to-tail fashion (referred to as type S) (Fig. 4A). Interestingly, in the CTD2 form which crystallized at pH 8.5, a similar contact is observed between three of the four crystallographically independent dimers (Fig. 4B). However, unlike in CTD1, where the dimers form an infinitely long linear array, a small swivel between the three CTD2 dimers (dimers 1, 2, and 3) introduces a slight curvature. In both crystal forms, type S interactions are mediated by C-terminal residues located between positions 308 and 328, which include α helix α5 and a type II turn. A network of water-mediated polar interactions and a salt bridge between residues Arg 308 and Asp 314 are observed (Fig. 4A, bottom). Secondly, a lateral interaction between dimers 2 and 4 (Fig. 4B) mediated by their N-terminal residues (221 to 230) buries a comparable surface area of ~1,250 Å² (type L). Dimer 4 extends the helical array formed by dimers 1, 2, and 3 in a lateral manner (Fig. 4B [type S’]). Finally, in the CTD3 crystal form, dimers form a long helical polymer that spirals along the 4, screw axis, with a buried surface area of ~1,085 Å² (type F). These interactions mediated by hydrogen bonds between Arg 230 of one monomer and carbonyl atoms from residues 263 to 266 in the other monomer bear some resemblance to the type L interactions seen in CTD1 and CTD2. These contacts result in an infinitely propagating tube of CTD3 molecules with a diameter of approximately 60 Å (Fig. 4C and 5B). Interestingly, this arrangement of CTD subunits would place the RNA binding N-terminal domains towards the interior of the tube and the C-terminal domains pointing outside.

DISCUSSION

A flexible filamentous nucleocapsid formed by the close association of N proteins with viral genomic RNA is a common feature in many enveloped ssRNA viruses including coronaviruses. Structural information on the N protein and a molecular
understanding of how this protein facilitates the formation of the nucleocapsid are limited. From the biochemical characterization of the N protein of IBV, a prototypical coronavirus, presented here, it is apparent that this protein has two major protease-resistant domains. Our X-ray crystallographic analysis of these two domains, NTD and CTD, provides some insights into how the two-domain organization of the N protein may coordinate nucleocapsid assembly.

Interaction of N with RNA. Biochemical studies (14, 29) have located the RNA binding site in the N-terminal domain with the minimal region being mapped to residues 177 to 231 in MHV (corresponding to residues 136 to 190 in IBV). In addition to the NTD, an involvement of the CTD in RNA binding has been shown by Fan et al. (14). Based on the structure of the NTD (IBV Beaudette strain), we proposed that the basic arms of the U-shaped monomer participate in RNA binding. This hypothesis is consistent with an NMR-heteronuclear single quantum coherence analysis of NTD-RNA interactions that was carried out for the SARS coronavirus N protein (18). A novel finding from our crystal structure analysis is the presence of strong interlocking dimers of the NTD (IBV Gray strain). This is in contrast with the weak dimeric interaction observed in the NTD of the IBV Beaudette strain reported earlier (14). These interlocking dimers associate to form a linear fiber with the basic tethers exposed along the surface. Such fibers could provide for closely packed interactions of NTD with the viral genomic RNA. Analysis of N protein-RNA interactions in MHV at different stages of the virus life cycle revealed that these interactions progress from an RNase-sensitive complex involving subgenomic RNA to an RNase-resistant complex involving genomic RNA (28). The strong and weak NTD dimer interactions seen in the two structures could correspond to these different states of N protein-RNA associations. The electrostatic potential surface of the CTD dimer shows one of its faces significantly more basic than the other, with a groove lined by α-helices α3 and α4 that could interact with RNA (Fig. 2 and 5A and B).

FIG. 4. Crystal-packing interactions between CTD dimers. (A) Crystal-packing interactions in CTD1 crystals grown at pH 4.5, with one dimer in the asymmetric unit (ASU). Three consecutive dimers from the neighboring ASU (numbered n, n+1, and n−1) related by one of the three orthogonal 21 screw axes are shown (type-S interaction). Each monomer has been given a different color. The N- and C-terminal ends for the n+1 are indicated. The salt bridge interaction between dimers n and n−1 seen in the type-S interface is circled. A closeup view of the salt bridge interaction with an electron density map is shown in the inset below. (B) Interactions between the four CTD dimers present in the CTD2 ASU (pH 8.5). Each dimer is shown in a different color and numbered from 1 to 4. The two classes of dimer-dimer interactions are indicated by S (between molecules 1 and 2 and molecules 2 and 3) and L (between molecules 2 and 4). The bridging type-S interactions are shown with molecule 4 from two adjacent ASUs and molecules 1, 2, and 3 from the neighboring ASU (all shown in gray). (C) Dimer-dimer interactions observed in the CTD3 crystals having one CTD dimer in the ASU (type F). Each dimer related by the crystallographic 43 screw axis is shown in a different color. This type of packing gives rise to hollow tubes, as is evident from a projection along the fiber axis (along the c axis) below shown in red.
Interaction between the N and M proteins. In addition to their interactions with RNA, N proteins also interact with the M proteins embedded in the viral membrane. Based on reverse genetic-complementation assays, the interaction region between these two proteins has been mapped to their C termini (19). The C terminus of the M protein is significantly basic, and recent mutational studies on the M protein have demonstrated that its interaction with the N protein is predominantly electrostatic in nature (26). The exposed acidic β-sheet floor, on the opposite side of the proposed RNA-binding region in the CTD dimer, may promote such an interaction. Thus, the CTD may serve a dual purpose of mediating the self-association of the N protein during nucleocapsid formation but also of providing a complementary surface for interaction with the endodomain of the M protein in the virus envelope.

Possible model for nucleocapsid formation. The formation of the coronavirus nucleocapsid involves self-association of the N protein and interaction with RNA resulting in a structure which is RNase resistant. Our crystal structure analysis of CTD reveals a tight dimer mediated by an exchange of secondary structure elements (domain swapping), thus suggesting that the full-length N protein also functions as a dimer, with the CTD providing a structural scaffold while the NTD mainly serves as a module for RNA interaction. The relative orientation of the NTD with respect to the CTD in the full-length protein remains unknown, because in the full-length protein these two domains are connected by a 47-residue protease-sensitive loop, rich in Ser and Gly residues, which is presumably mobile. In the filamentous ribonucleocapsid, thanks to the flexibility provided by this linker, the RNA binding regions of these two domains could face each other, engulfing the RNA between them, thus conferring resistance to RNases.

In the various crystal forms studied, the NTD and CTD self-associate in multiple modes with buried surface areas greater than 1,000 Å². A relevant question is which (if any) of these interactions are used in the formation of the nucleocapsid. Both the type-S and -F interactions between CTDs are conducive to the formation of fibril structures. Propagation of
any single type of interactions, however, would lead to a rigid helical nucleocapsid. Considering that the coronavirus nucleocapsid is not a rodlike structure, nucleocapsid assembly may thus involve a combination of the various interactions observed in our studies. The type-S interface could be used to a greater extent given that it occurs over a wider range of pH and seems to form regardless of the constraints imposed by crystal-packaging forces (as in the CTD2 crystals). A combination of the type-S interactions with types L and F would modulate the curvature of the nucleocapsid in the virion (Fig. 5C).

**Similarity with other coronavirus N proteins.** Coronaviruses have been classified into four groups, with SARS-CoV being the founding member of an independent group. The N protein sequences are more similar within each group (40% identity) than across groups (20 to 30% identity). The only X-ray structure of a coronavirus N protein available to date is that of the IBV NTD protein as described here and by Fan et al. (14). Despite very low sequence similarity between IBV and the SARS-CoV N proteins, their NTD and CTD structures adopt the same general polypeptide fold. This suggests that this fold is essentially preserved across the various coronavirus groups. This conclusion is also consistent with the NMR structures of the N- and C-terminal domains of the SARS N protein reported recently (4, 18).

**Comparison with the N proteins of other positive-strand ssRNA viruses.** Crystal structures of nucleocapsid proteins from several other positive-strand ssRNA viruses, including porcine reproductive and respiratory syndrome virus (PRRSV) in the *Arteriviridae* (11), West Nile virus in the *Flaviviridae* (12), and Sindbis virus and Semliki Forest virus in the *Togaviridae* family (6, 7), have been reported. The C-terminal domains of nucleoproteins from Sindbis virus and Semliki Forest virus adopt a chymotrypsin-like β-barrel core. Core proteins from West Nile and dengue virus are dimers composed entirely of α-helical bundles. As indicated by a systematic structural homology search (17), the coronavirus N protein CTD closely resembles the nucleocapsid protein of PRRSV. The PRRSV capsid-forming domain (C-terminal 73 to 123 amino acid residues) has a similar dimeric structure and exhibits self-association mediated by a salt bridge as seen in the IBV CTD (11) (Fig. 5D). Although a “domain-swapping” mode of oligomerization has been observed in a variety of proteins which are known to self-aggregate (24), the nature of domain swapping observed in these two viral proteins appears to be unique.

Interestingly, unlike the CTD fold which is shared with the arterivirus PRRSV, the fold of the NTD is observed only in the coronavirus N proteins (14). The corresponding basic N-terminal RNA binding domain in the much shorter PRRSV N protein appears to be largely disordered (11). Thus, the observed structural similarity between the N proteins of IBV and PRRSV suggests that members of the *Coronaviridae* and *Arteriviridae* families (order *Nidovirales*) share a common mechanism of filamentous nucleocapsid formation with suitable alterations necessary to interact specifically with their respective genomes. Conversely, the structural differences with other nucleocapsid proteins from ssRNA enveloped viruses, such as flaviviruses and togaviruses, probably reflect variations in their replication strategies and assembly pathways. Indeed, flaviviruses and togaviruses exhibit icosahedrally symmetric exteriors and are not pleomorphic like coronaviruses (27, 46). One common feature in the nucleocapsid proteins across positive-strand ssRNA viruses, however, appears to be the partitioning of the nucleocapsid protein structure into two domains: one forming a protective scaffold around the RNA through self-association and the other providing specific interactions with the viral genome. Electron-microscopic studies of ribonucleocapsid assemblies at higher resolution are now needed in order to gain further insights into the molecular mechanism of nucleocapsid formation for coronaviruses. However, we hope that the atomic description of the N protein provided here will stimulate such studies and also the design of molecules that could disrupt viral assembly.

**ACKNOWLEDGMENTS**

This work was supported by grants from the NIH (AI36040) and the Robert Welch Foundation to B.V.V.P. and grants from the Singapore Biomedical Research Council (03/1/22/17/220) and the Academic Research Fund (RG119/05) to J.L.

We thank Jennifer Falon and Florante Quiocio for use of the in-house X-ray diffraction facility at BCM. H.J. wishes to thank Chris Miller and HHMI for support during the latter half of this project. We acknowledge use of the SBC-CAT 19ID and BIOCARS BM14 beamline and we acknowledge its staff for their help during data collection at the Advanced Photon Source supported by the U.S. Department of Energy, Basic Energy Sciences, Office of Science, under contract no. W-31-109-Eng-38.
