SUMMARY

Many viruses induce hepatitis in humans, highlighting the need to understand the underlying mechanisms of virus-induced liver pathology. The murine coronavirus, mouse hepatitis virus (MHV), causes acute hepatitis in its natural host and provides a useful model for understanding virus interaction with liver cells. The MHV accessory protein, ns2, antagonizes the type I interferon response and promotes hepatitis. We show that ns2 has 2′,5′-phosphodiesterase activity, which blocks the interferon-induced OAS-RNase L pathway to facilitate hepatitis development. Ns2 cleaves 2′,5′-oligoadenylate, the product of OAS, to prevent activation of the cellular endoribonuclease RNase L and consequently block viral RNA degradation. An ns2 mutant virus was unable to replicate in the liver or induce hepatitis in wild-type mice, but was highly pathogenic in RNase L deficient mice. Thus, RNase L is a critical cellular factor for protection against viral infection of the liver and the resulting hepatitis.

INTRODUCTION

Many viral infections induce acute and/or chronic liver pathology in humans, for which there are often no known effective therapies or vaccines. There is little known about the early virus-host interactions that determine whether an infection is established, highlighting the need to understand mechanisms regulating the pathogenesis of viral hepatitis. The liver is constantly exposed to intestinal derived antigens present in the blood circulating through the liver sinusoids and, therefore, has evolved a unique immune environment that is relatively tolerant to foreign antigens and permissive to chronic infections (Crispe, 2009; Neumann-Haefelin et al., 2007). Thus, the innate immune response is a particularly important defense against pathogen invasion of the liver. Type I interferon (IFN) is the first line of defense available to restrict viral infection including infections with human hepatitis viruses (García-Sastre and Biron, 2006; Qu and Lemon, 2010). Kupffer cells (liver macrophages) found in the liver sinusoids are among the first cells to encounter viruses and as such, along with endothelial cells present a barrier that must be breached in order to access hepatocytes in the liver parenchyma (Crispe, 2009). Indeed, it has been reported that IFN signaling in macrophages is crucial for control of hepatitis induced by mouse hepatitis virus (Cervantes-Barragán et al., 2009) and lymphocytic choriomeningitis virus (Lang et al., 2010).

Type I IFN, primarily IFN-α/β, produced by virus-infected cells, induces expression of over four hundred interferon-stimulated genes (ISGs), whose products cooperate to induce an antiviral state. One potent antiviral IFN induced activity is the 2′,5′-oligoadenylate synthetase-ribonuclease L (OAS-RNase L) pathway (Sadler and Williams, 2008) (Figure 1). After infection, IFNs induce a group of OAS genes whose products are activated by viral double-stranded RNA (dsRNA). OAS uses ATP to generate the 2′,5′-linked oligoadenylates with the structures [p,5′A(2′p5′A)x; x = 1–3; n ≥ 2(2-5A)]. 2-5A binds to the ubiquitous cellular endoribonuclease RNase L, causing inactive RNase L monomers to form activated dimers (Dong and Silverman, 1995). RNase L cleaves single-stranded regions of both viral and cellular messenger RNA (mRNA), leading to inhibition of viral replication and protein synthesis (Silverman, 2007). In addition, detection of the newly generated short RNAs by cellular pattern recognition receptors, MD5 and RIG-I, further enhances IFN production and the ensuing antiviral activities (Malathi et al., 2007). The concentration of 2-5A is believed to be the primary factor controlling RNase L activation. The cellular enzyme 2′-phosphodiesterase (2′-PDE, also known as PDE12) has been proposed to reduce or prevent 2-5A-mediated activation of RNase L by degrading 2-5A, presumably to prevent excessive tissue damage caused by the effects of RNase L (Kubota et al., 2004). The antiviral activity of the OAS-RNase L pathway has been demonstrated during infections of mice with numerous RNA and DNA viruses (Floydström-Tullberg et al., 2005; Li et al., 1998; Samuel et al., 2006; Scherbik et al., 2006; Washenberger et al., 2007; Xiang et al., 2002; Zhou et al., 1997).

Hepatitis caused by the murine coronavirus, mouse hepatitis virus (MHV), is an acute disease induced in the natural host and provides a convenient and valuable model for understanding the interaction of virus with liver cells (Weiss and Leibowitz, 2011). Previous studies using reverse genetics and MHV strains with different tropisms demonstrated that events that occur after viral entry play a crucial role in the likelihood of liver invasion and the development of hepatitis (Navas and Weiss, 2003). Indeed, we recently reported that MHV accessory protein ns2 confers the ability to antagonize the type I IFN antiviral response in macrophages and that this is required for efficient viral replication in the liver and the development of hepatitis (Zhao et al., 2011). Based on sequence homology to cellular phosphodiesterases, ns2 had been predicted to be a cyclic phosphodiesterase (Mazumder et al., 2002; Snijder et al., 2003). We show here that ns2 has in fact a 2',5'-phosphodiesterase activity that can downregulate intracellular levels of 2-5A, thereby preventing the activation and antiviral activity of RNase L. Our results underscore the importance of the OAS-RNase L pathway in vivo for protection of the host from developing viral hepatitis.

RESULTS

MHV A59 Resists RNase L Activity

MHV differs from many other viruses in that it stimulates type I IFN production in only limited cell types, primarily in macrophages (Roth-Cross et al., 2008) and plasmacytoid dendritic cells (Cervantes-Barragan et al., 2007). Furthermore, MHV displays cell type-specific sensitivity to the antiviral effects of IFN treatment, with macrophage lineage cells being the most successful in restricting MHV replication (Rose and Weiss, 2009; Zhao et al., 2011). We also observed that MHV was unable to prevent IFN induction by a coinfected virus and was also unable to protect against the effects of IFN (Roth-Cross et al., 2007). Thus, we reasoned that MHV is unable to subvert major IFN signaling pathways, but rather may interfere with one or more IFN-induced antiviral activities. Indeed, a previous study showed that MHV-A59 infection does not promote RNase L-mediated degradation of 18S and 28S ribosomal RNA (rRNA) in HeLa cells (Ye et al., 2007), suggesting that the OAS-RNase L pathway may be downregulated. To more directly evaluate the role of RNase L in MHV replication, we compared the replication of wild-type A59 in bone-marrow derived macrophages (BMMs) from wild-type C57BL/6 (B6) mice or from mice genetically ablated for RNase L expression [RNase L−/− (B6)]. The kinetics of accumulation of A59 genome RNA were indistinguishable in the two cell types (Figure 2A), as was the extent of infectious virus replication (Figure 2D).

Figure 1. The Interferon-Induced OAS-RNase L Pathway

After infection, viral RNA is detected by pattern recognition receptors RIG-I and MDA5, resulting in the induction of IFN-α/β, which in turn induces ISGs, including OAS. OAS is activated by dsRNA to produce 2-5A, which activates RNase L. RNase L degrades cellular and viral RNA producing more RNA that is recognized by MDA5 and RIG-I, resulting in enhanced IFN induction. 2'-PDE cleaves 2-5A and inhibits the activation of RNase L. MHV ns2, like the cellular enzyme 2'-PDE, is a 2',5'-phosphodiesterase. OAS, 2',5'-oligoadenylate synthetase; 2-5A, 2',5'-oligoadenylate; 2'-PDE, 2'-phosphodiesterase.

Figure 2. MHV Replication Is Not Inhibited by RNase L Signaling

(A–C) BMMs from B6 or RNase L−/− mice were infected with MHV-A59, SeV, or EMCV (1 PFU/cell). At the indicated time points, RNA was isolated from cell lysates and viral mRNA expression quantified by qRT-PCR (n = 3). Relative viral mRNA expression levels were expressed as 2^ΔΔCT, relative to β-actin mRNA [ΔΔCT = CT(gene of interest) − CT(β-actin)] − CT(B6−/−).

(D) Cells infected with MHV-A59 were lysed by freeze-thawing and titers determined by plaque assay (n = 3). See also Table S1.
We showed previously that A59 ns2 antagonizes the IFN-α/β signaling pathway in macrophage lineage cells (Zhao et al., 2011). Furthermore, the A59 mutant virus, ns2-H126R, carrying a single amino acid substitution in a predicted phosphodiesterase catalytic His residue (Mazumder et al., 2002; Roth-Cross et al., 2009; Snijder et al., 2003), is attenuated for replication in BMMs derived from B6 and RNase L−/− mice. Along with robust replication of A59 in B6 BMMs (Figure S1), we observed extensive lysis of most of the cells by 48 hr postinfection (p.i.), while most of ns2-H126R-infected BMMs remained intact (Figure 3C). The few cells left intact after A59 infection expressed viral antigen, while there were small numbers of cells expressing viral antigen after ns2-H126R infection. In contrast, in RNase L−/− BMMs, ns2-H126R recovered the ability to replicate efficiently, with similar kinetics (Figure 3A) and induced similar wide spread cell lysis as A59 (Figure 3C). Similar results were obtained for two other mutants carrying single amino acid substitutions in ns2, H46A, and L94P (Figure S1 available online). These data suggest that ns2 confers the ability to antagonize the antiviral activities of RNase L.

To gain further insight into the mechanism of ns2 action, we compared the replication of A59 and ns2-H126R in mice genetically ablated for expression of PKR (protein kinase R), a potent antiviral mediator that like OAS is bound and activated by dsRNA (Sadler and Williams, 2008). A59 replicated to 10-fold higher titers in PKR−/− as compared to B6 BMMs, indicating that MHV is sensitive to the antiviral effects of PKR. However, the replication kinetics of ns2-H126R in PKR−/− BMMs were the same as in B6 BMMs (Figure 3B), indicating that ns2 does not antagonize PKR, but rather specifically inhibits the OAS-RNase L pathway. Together with the results obtained in the RNase L−/− BMMs (Figure 3A), these data imply that ns2 acts through a mechanism other than that employed by other viral proteins, including vaccinia E3L (Chang et al., 1992; Xiang et al., 2002) and influenza ns1 (Lu et al., 1995; Min and Krug, 2006), which inhibit both OAS and PKR activity by binding and sequestering dsRNA.

**Ns2 Inhibits RNase L Cleavage by Decreasing 2-5A Levels**

In order to compare the extent of RNaseL activity during A59 and ns2-H126R infection, we compared the state of cleavage of rRNA in B6 BMMs infected with either ns2-H126R or A59. RNA chip analysis of infected BMMs showed that ns2-H126R induced obvious rRNA cleavage at 9 and 12 hr p.i. In contrast, A59 did not induce RNA cleavage above background even at the later time points, indicating that ns2 efficiently inhibits RNA cleavage (Figure 4A). As expected, neither virus induced rRNA cleavage in RNase L−/− BMMs (Figure S2A), confirming the cleavage was RNase L mediated.

Latent RNase L is activated by 2′,5′-linked oligoadenylate (2-5A), which is synthesized by OAS upon activation with dsRNA (Silverman, 2007). To further investigate whether ns2 directly inhibits accumulation of 2-5A, through its predicted phosphodiesterase activity (Mazumder et al., 2002), we measured intracellular levels of 2-5A with A59 or ns2-H126R in BMMs derived from B6 (Figure 4C) and RNase L−/− (Figure 4D) mice. In both B6 and RNase L−/− BMMs, the concentration of 2-5A in ns2-H126R-infected cells was significantly higher than that in A59-infected cells. It should be noted that the 2-5A concentration in RNase L−/− BMMs, as measured by activation of RNase L in a fluorescence resonance energy transfer (FRET)-based assay (see the Experimental Procedures) after infection with either viral strain was much lower than that in virus-infected B6 BMMs (Figure 4D), probably because induction of optimal OAS levels is dependent on an active OAS-RNase L pathway (Malathi et al., 2007).

To directly assess the effects of ns2 on the level of 2-5A, we transfected ns2- and ns2-H126R-expressing plasmids...
separately into HEK293T cells. Staining with anti-ns2 monoclonal antibody (obtained from Dr. Stuart Siddell, University of Bristol) demonstrated similar expression levels of WT and H126R mutant ns2 (Figure S2B). The OAS-RNase L pathway was subsequently activated in ns2-expressing cells by treatment with IFN and transfection of poly(rI):poly(rC) [poly(I:C)], which mimics naturally occurring dsRNA in activating OAS activity, and the level of RNase L mediated cleavage of rRNA assessed. The expression of ns2 but not ns2-H126R mutant protein in 293T cells decreased the extent of rRNA cleavage as compared with empty vector-transfected cells (Figure 4B). In addition, the level of 2-5A in ns2-transfected cells was significant lower (p < 0.001) than that in empty vector- or ns2-H126R mutant-transfected cells (Figure 4E). Taken together, these results demonstrate that ns2 inhibits RNase L-induced cleavage by limiting the amount of available 2-5A.

**Ns2 Degradates 2-5A into ATP and AMP**

Previous studies reported that the cellular protein 2′-phosphodiesterase (2′-PDE) degrades 2-5A into AMP and ATP and was presumed to regulate the level of RNase L activity (Kubota et al., 2004). Since ns2 was predicted to have phosphodiesterase activity, we hypothesized that ns2 could display a similar enzymatic activity to 2′-PDE and directly cleave 2-5A, thus reducing the activation of RNase L. To test this hypothesis, we expressed ns2, ns2-H126R, and murine 2′-PDE in E. coli and purified the recombinant proteins as described in the Supplemental Experimental Procedures. Each protein was incubated with trimer 2′-5A (2′-5′)pA3, and at several time points the degradation products were monitored by a high-performance liquid chromatography (HPLC) assay. ns2 and murine 2′-PDE, but not ns2-H126R, degraded 2-5A to the final products of AMP and ATP (Figures 5A–5C). As confirmed by FRET assays (Thakur et al., 2005), the quantity of (2′-5′)pA3 remaining was significantly decreased after incubation with both ns2 and murine 2′-PDE but not ns2-H126R inactive protein (Figure 5D). These findings demonstrated that ns2 has specificity for 2′,5′-phosphodiester bonds and can directly degrade 2-5A with similar kinetics as 2′-PDE.

**Inhibition of the OAS-RNase L Pathway Is Required for MHV Replication and Spread In Vivo**

Our previous studies demonstrated that after intrahepatic (IH) inoculation of A59, viral replication is robust in the liver by 3 days postinfection (d.p.i.), peaks at 5 d.p.i., and is mostly cleared by 7 d.p.i. (Navas et al., 2001; Roth-Cross et al., 2009). In contrast, ns2-H126R replicates minimally in the liver (Roth-Cross et al., 2009; Zhao et al., 2011). However, in mice depleted of macrophages prior to infection, ns2-H126R replication and induction of hepatitis were significantly enhanced, approaching that of A59 (Zhao et al., 2011). Taking these in vivo data in combination with the finding that ns2-H126R replicates minimally in B6 BMMs (Figure 3A) (Zhao et al., 2011), we speculated that the ability to replicate in Kupffer cells (liver macrophages) was a prerequisite for spread of virus into the liver parenchyma and for the consequent development of hepatitis. Since ns2-H126R recovers the ability to replicate in RNase L−/− BMMs (Figure 3A), we predicted that the ns2 mutant virus would also replicate and spread in the absence of RNase L activity in vivo. For testing of this hypothesis, both B6 and RNase L−/− mice were inoculated IH with 200 PFU of either A59 or ns2-H126R and virus titers in the liver were quantified. In B6 mice, A59 replicated to high titers...
In RNase L−/− mice, ns2-H126R replicated near the limit of detection. In contrast, in RNase L−/− mice, ns2-H126R reached titers, comparable to those attained by A59 (Figure 6A), reflecting that wild-type ns2 expression is not necessary for efficient replication in the absence of RNase L expression. Notably, there was no significant difference in A59 titers between livers of B6 and RNase L−/− mice (Figure 6A), indicating that ns2 is efficient at antagonizing RNase L activation in B6 mice. Surprisingly, however, by 7 d.p.i., there were striking differences in viral clearance between B6 and RNase L−/− mice. While both viruses were nearly cleared from the liver of B6 mice at 7 d.p.i., there were still considerable titers of both A59 and ns2-H126R in the livers of RNase L−/− mice (Figure 6A).

Consistent with viral titers, in B6 mice, A59 expresses abundant viral antigen at 5 d.p.i., which is mostly cleared at 7 d.p.i., while ns2-H126R expresses minimal if any viral antigen. In contrast, in RNaseL−/− mice, both viruses express viral antigen at 5 d.p.i. to a similar extent as in B6 mice (Figure 6B). However instead of clearing virus at 7 d.p.i., both viruses expressed increase viral antigen compared to 5 d.p.i. These data indicate that ns2-mediated antagonism of RNase L activation confers the ability to replicate in the liver, but complete genetic ablation of RNase L expression in mice has additional effects on viral clearance.

The patterns of replication of A59 and ns2-H126R in the spleen, lung, and kidney of B6 mice were similar to those in the liver; ns2-H126R replicated minimally, while A59 replicated efficiently, although not to as high titers as in the liver (Figure 6A). There were no significant differences between A59 and ns2-H126R replication in the spleen, lung, and kidney of RNase L−/− mice at all times tested (Figure 6A), and viral antigen expression in the spleen confirmed that the viral replication and spread for ns2-H126R were similar to those of A59 in the RNase L−/− mice (Figure S3A).

As in comparison of replication in the liver, B6 and RNase L−/− mice showed no difference in infectious A59 titers in the lung and kidney at 3 and 5 d.p.i. However, the A59 titer in the spleen at both 3 and 5 d.p.i of RNase L−/− mice was 10-fold higher than that in B6. This may be at least in part due to the previously reported reduced level of apoptosis in the spleen of RNaseL−/− mice (Zhou et al., 1997). Though not statistically significant, the low, but detectable titers of virus at 7 d.p.i. in the spleen, lung, and kidney of RNase L−/− mice were all higher than in B6 mice, perhaps resulting from the delayed clearance in the liver.

**Inhibition of the OAS-RNase L Pathway Is Required for the Induction of Hepatitis**

Viral replication in the liver is associated with induction of hepatitis. Indeed, necrotic foci and parenchymal inflammation were observed in liver sections from A59 infected B6 mice sacrificed at 5 d.p.i. (Figures 7A and 7B). Similar pathology was observed in sections from A59- or ns2-H126R-infected RNase L−/− mice at 5 d.p.i., while liver sections from ns2-H126R-infected B6 mice, exhibited no obvious pathological changes (Figure 7A). However, as might be predicted by the lack of viral clearance from the livers of RNase L−/− mice, there was extensive necrosis and inflammation in A59- or ns2-H126R-infected livers from RNase L−/− mice compared with the few necrotic foci in the A59-infected livers and the absence of pathology in ns2-H126R-infected livers from B6 mice at 7 d.p.i. (Figure 7A). Consistent with the pathology, staining with anti-caspase-3 antibody demonstrated extensive apoptosis around necrotic foci in A59-infected livers from both B6 and RNase L−/− mice, but only in livers of RNase L−/− mice infected with ns2-H126R (Figure 7B).

Inflammation in the liver is associated with the local production of inflammatory cytokines, especially TNF-α and IFN-γ (Das et al., 2009). The patterns of cytokine mRNAs induced by A59 and ns2-H126R were consistent with the levels of necrosis and inflammation observed above. There were no differences in the
induction of TNF-α and IFN-γ mRNAs in the livers of A59-infected B6 and RNase L−/− mice at 3 and 5 d.p.i., while ns2-H126R induced only minimal levels of both cytokines in livers of B6 mice. A59 and ns2-H126R induced similar levels of TNF-α and IFN-γ mRNAs in the livers of RNase L−/− mice (Figure 7C), indicating, as expected, that ns2-H126R induced the same extent of hepatitis as A59, in the absence of expression of the OAS-RNase L pathway. However, there was a significantly higher (p = 0.0308) level of expression of IFN-γ mRNA in the liver of RNase L−/− mice compared with B6 mice at 7 d.p.i., consistent with the increased virus titers (Figure 6A) and necrosis (Figure 7A).

**DISCUSSION**

We present evidence for a molecular mechanism of subversion of the RNase L pathway in macrophages that regulates acute hepatitis during MHV infection. MHV and other closely related betacoronaviruses (de Groot et al., 2012) encode ns2 proteins that together with related proteins of toroviruses and human rotavirus form a protein family (known also as LigT-like or family II) with cellular proteins of diverse origins, some of which possess cyclophosphodiesterase (CPD) activity. The family is part of a larger superfamily of 2H phosphodiesterases characterized by the presence of a pair of conserved His-x-Thr/Ser motifs (Mazumder et al., 2002; Snijder et al., 2003). We were unable to demonstrate that ns2 has a CPD activity using as substrates 2',3'-cAMP, 3',5'-cAMP, and ADP-ribose 1',2'-cyclic phosphate (unpublished data), but instead found that ns2 is a 2',5'-phosphodiesterase cleaving, and thus eliminating, 2-5A, the activator of RNase L. In this respect, ns2 resembles the *E. coli* 2',5'-RNA ligase, also within the 2H phosphodiesterase superfamily, which can ligate 2',5'-phosphodiesterase reaction in vitro (Arn and Abelson, 1996). Before this study, 2',5'-PDE (PDE12) of the different exonuclease-endonuclease-phosphatase family (Goldstrohm and Wickens, 2008) was the only mammalian enzyme known that cleaves the 2',5'-bond in 2-5A. Accordingly it was proposed to be a key regulator of the OAS/RNase L system (Kubota et al., 2004). Thus, two proteins, 2',5'-PDE and ns2, both of which can cleave 2-5A, evolved independently. It remains to be seen whether other incompletely characterized homologs of ns2 of the viral and cellular origins have similar substrate specificity.

Substitution of the catalytic His residue (H126R) of ns2 abrogated phosphodiesterase reaction in vitro (Arn and Abelson, 1996). Before this study, 2',5'-PDE (PDE12) of the different exonuclease-endonuclease-phosphatase family (Goldstrohm and Wickens, 2008) was the only mammalian enzyme known that cleaves the 2',5'-bond in 2-5A. Accordingly it was proposed to be a key regulator of the OAS/RNase L system (Kubota et al., 2004). Thus, two proteins, 2',5'-PDE and ns2, both of which can cleave 2-5A, evolved independently. It remains to be seen whether other incompletely characterized homologs of ns2 of the viral and cellular origins have similar substrate specificity.

Substitution of the catalytic His residue (H126R) of ns2 abrogated phosphodiesterase activity in vitro (Figure 5) as well as virus replication in macrophages and in the livers of B6 mice (Zhao et al., 2011), demonstrating that the enzymatic activity of ns2 was necessary for the type I IFN antagonism and virulence conferred by ns2. Two additional ns2 mutant viruses, one with H46A substitution of the second predicted catalytic His residue (Roth-Cross et al., 2003).
mice varies among viruses and cell types (Silverman, 2007; Zhou et al., 1997). HIV (Martinand et al., 1999) and EMCV (Martinand et al., 1998) induce expression of an RNome L inhibitor protein, RLI (a.k.a. ABCE1). However, RLI is apparently less efficient than ns2 in the control of RNome L activity during EMCV infections (Figure 2). The group C enterovirus genome contains a conserved RNA structure that inhibits the activity of RNome L (Townsend et al., 2008). Herpes simplex virus I (Cayley et al., 1984) and SV40 (Hersh et al., 1984) induce synthesis of 2-5A derivatives that antagonize or fail to activate RNome L. Vaccinia E3L protein antagonizes OAS by reducing the level of dsRNA available and successfully escapes the effects of RNome L (Xiang et al., 2002). Based on the finding that the A59 nucleocapsid (N) protein could functionally replace the E3L protein in rescuing vaccinia virus ∆E3L from the antiviral effects of IFN, it was suggested that N could also bind dsRNA, thus interfering with the activation of OAS (Ye et al., 2007). However, expression of N protein, in the context of MHV infection, is clearly not potent enough to shut down OAS-RNome L pathway as ns2-H126R induces RNome L-mediated cleavage of rRNA in BMMs (Figure 4A). In contrast, rRNA cleavage was not detectable in A59 infected BMMs, providing further evidence that ns2 is a potent antagonist of the OAS-RNome L pathway. The comparable level of A59 replication in B6 and RNome L-/-BMMs and in the infected liver at least through 5 d.p.i. suggests that ns2 is able to completely antagonize RNome L activity, although there may be cell types in which this is not complete. Our findings demonstrate a mechanism by which the OAS-RNome L pathway can be antagonized, that is by blocking the activation of RNome L through the ns2-mediated cleavage of 2-5A.

Figure 7. MHV ns2 Facilitates the Induction of Viral Hepatitis in vivo
(A) Livers sections from mock or virus-infected mice sacrificed at 5 and 7 d.p.i. were stained with hematoxylin and eosin (H&E). Arrows show areas of necrosis. The scale bar represents 500 μm. Sections are representative of two sections from three animals from each group.
(B) Liver sections from mice sacrificed at 5 d.p.i. were stained with H&E for detection of inflammation or with anti-caspase-3 antibody for detection of apoptosis. The scale bar represents 100 μm. Sections are representative of two sections from three animals from each group.
(C) Livers were harvested from mock- or virus-infected mice (n = 5) at 3, 5, and 7 d.p.i., and RNA was isolated. TNF-α and IFN-γ mRNAs were quantified by qRT-PCR, normalized to β-actin mRNA level, and expressed as the fold change relative to mock infected with the formula 2^[-ΔΔCt]. Viruses have evolved multiple mechanisms for inhibiting RNome L. Thus, the susceptibility to RNome L in vitro and in
expression of mRNAs for genes encoding active OAS proteins (Kakuta et al., 2002), OAS1a, OAS2, and OAS3, were also higher in macrophages as compared with primary hepatocytes (data not shown) (Asada-Kubota et al., 1998). We hypothesize that Kupffer cells serve as a gateway to restrict entrance from the sinusoids into the liver parenchyma. Indeed, it has been reported that IFN signaling in macrophages is crucial for control of hepatitis induced by MHV (Cervantes-Barragán et al., 2009) as well as LCMV (Lang et al., 2010). We propose that upon infection of Kupffer cells, the IFN response, most importantly the OAS-RNase L pathway, creates an antiviral state restricting infection and limiting spread of virus to the parenchymal hepatocytes, thus preventing hepatitis. However, ns2 facilitates viral replication in Kupffer cells by antagonizing the OAS-RNase L pathway, thus downregulating the IFN response and enhancing entry into the liver parenchyma. Depletion of macrophages confers susceptibility to ns2-H126R as well as increased susceptibility to A59 (Zhao et al., 2011), supporting the notion that the Kupffer cells provide protection against invasion of the liver parenchyma.

After intracranial inoculation, ns2 mutants replicate to the same titers as A59 in the brains of B6 (Roth-Cross et al., 2009) and RNase L+/− mice (data not shown), implying that antagonism of RNase L is not required for efficient MHV replication in the brain. However, we found that clearance is delayed in the brains (data not shown) as in the livers (Figure 6A) of RNase L+/− mice. Similarly, the MHV-JHM v-2.2 variant replicated to a similar titer in the CNS during acute infection of B6 and RNaseL−/− mice; however, v-2.2 spread into microglia/macrophages within the gray matter of the spinal cord and induced more demyelination in RNase L+/− mice than in B6 mice (Ireland et al., 2009). (While there are no published data on ns2 expression by v-2.2, it is very likely to express an active ns2 as the closely related JHMv2.2 variant replicated to a similar titer in the CNS during acute infection of B6 and RNaseL−/− mice; however, v-2.2 spread into microglia/macrophages within the gray matter of the spinal cord and induced more demyelination in RNase L+/− mice than in B6 mice (Ireland et al., 2009).) These findings support our previous conclusion that the requirement for ns2 expression for MHV virulence is organ specific (Zhao et al., 2011); they also show that basal levels of RNase L expression are required for efficient MHV clearance in the brain as well as the liver (Figure 6).

Our results underscore the important role of RNase L in host restriction of viral infection of the liver. The success of IFN-α/β treatment of chronic hepatitis C virus (HCV) may depend in part on the susceptibility of viral RNA genome to degradation by RNase L, which cleaves single-stranded viral RNA on the 3′ sides of UU and UA dinucleotides. Cleavage of HCV genome RNA by RNase L releases a small RNA that is recognized by RIG-I and thus serves to enhance IFN induction (Malathi et al., 2010). Indeed, the strains of HCV that are most susceptible to IFN-α/β treatment are those strains with genomes predicted to be most vulnerable to RNase L-mediated degradation (Han et al., 2004; Wasenberger et al., 2007). Thus, enhancement of the activity of the OAS-RNase L pathway may have potential for antiviral therapy for liver infections. A possible approach to enhancing RNase L mediated viral RNA genome degradation might be to limit activities of enzymes that degrade 2′-5′A; treatment with an inhibitor for 2′-PDE was shown to decrease vaccinia virus replication in vitro (Kubota et al., 2004). In this regard, inhibitors of virus-encoded phosphodiesterases that degrade 2′,5′-oligoadénylates could provide an avenue for development of targeted antiviral drugs.

## EXPERIMENTAL PROCEDURES

### Cell Lines, Viruses, and Mice

Murine L2 fibroblasts and HEK293T cells were cultured as described previously (Roth-Cross et al., 2007). Plaque assays were performed on murine L2 cell monolayers (Hingley et al., 1994). Recombinant coronaviruses inf-MHV-A59 (A59) and inf-ns2-H126R (ns2-H126R) have been described previously (Roth-Cross et al., 2009; Schwarz et al., 1990). (See the Supplemental Experimental Procedures for other ns2 mutants.) EMCV (Babu et al., 1985) was obtained from Dr. Sally Huber (University of Vermont), and Sendai virus (SeV), strain S2 (López et al., 2006), was obtained from Dr. Carolina Lopez (University of Pennsylvania). C57BL/6 (B6) mice were purchased from Jackson Laboratory. RNase L+/− mice (B6, ten generations of backcrossing) (Zhou et al., 1997) were bred in the University of Pennsylvania animal facility. PKR−/− mice (B6 background) (Yang et al., 1995) were a gift from Bryan R.G. Williams (Monash Institute, Melbourne).

### Plasmid Constructs

The ns2 and ns2-H126R open reading frames were ligated into mammalian expression vector pCAGGS, resulting in pC-ns2 and pC-ns2-H126R. The ns2 and ns2-H126R open reading frames (ORFs) were inserted into E. coli expression vector pMAL-c2, resulting in pMAL-ns2 and pMAL-ns2-H126R. The murine 2′-PDE-ORF cloned into pET-SUMO was obtained from Reinhard Seidlmeier, Ingenium Pharmaceuticals AG, Martinsried, Germany.

### BMM Isolation and Infection

Primary BMMs were generated from the hind limbs of B6 or RNase L−/− mice as described previously (Caamaño et al., 1999) and cultured in DMEM supplemented with 10% FBS and 20% L929 cell-conditioned medium for 6 days. BMMs were either mock infected or infected with 0.01 or 1 plaque forming units (PFU)/cell with A59 or ns2-H126R and harvested at time points indicated.

### Real-Time Quantitative RT-PCR

RNA was isolated with an RNeasy mini kit (QIAGEN). Quantitative RT-PCR (qRT-PCR) was performed with an iQ5 iCycler (Bio-Rad), and cycle threshold (Ct) values were recorded as described previously (Rose et al., 2010; Roth-Cross et al., 2007). Viral mRNA levels were expressed as relative to β-actin mRNA with the formula 2−ΔΔCt = 2−(Ct(geometric mean) − Ct(β-actin)). Cytokine mRNA expression levels were expressed as the fold change relative to mock-infected levels with the formula 2−ΔΔCt. The primers used in qRT-PCR are listed in Table S1.

### RNase L-Mediated Ribosomal RNA Cleavage in Intact Cells

For quantification of RNA cleavage, total RNA from virus-infected BMMs or transfected 293T cells (see the Supplemental Experimental Procedures) was isolated with the RNaseasy kit (QIAGEN) and quantified by Nanodrop analyzer. Equal quantities of RNA (500 ng) were separated on RNA chips and analyzed with an Agilent Bioanalyzer 2100 (Agilent Technologies) (Xiang et al., 2003).

### Quantification of 2′-5′A

2′-5′A was quantified by an indirect assay in which activation of RNase L activity is measured (Elbaeesh et al., 2011). In brief, cells were lysed in preheated (95 °C) buffer containing 1% Nonidet-P40 and clarified by centrifugation, and molecules >3 kDa were removed by centrifugation in Microcon filters. RNase L activity was determined with a FRET assay, with recombinant human RNase L and a cleavable substrate consisting of a 36 nucleotide synthetic oligoribonucleotide ([S]-6-FAMUUAACAAUUCUUUGCCCAUUUUUUUGGGUU-BHQ-1)-3′ derived from respiratory syncytial virus (Thakur et al., 2005). A standard curve was generated with an authentic 2′-5′A standard (95% purity), and fluorescence was measured with a Wallac 1420 fluorimeter (Perkin-Elmer LAS).

### 2′-PDE Activity Assay

2′-PDE activity was quantified by monitoring of the degradation of purified (2′-5′)-pA2 with HPLC (Molinaro et al., 2006) or the FRET-based RNase L activity assay, as above (Thakur et al., 2005) (see the Supplemental Experimental Procedures). For the 2′-PDA degradation assay, 100 μM purified (2′-5′)-pA2 was incubated for the indicated time with 10 μg/ml purified ns2,
Cell Host & Microbe
RNase L Antagonist Is Required for Viral Hepatitis

ns2-H126R, or 2’-PDE protein and then centrifuged in microcon centrifugal filter MWCO 3kDa (Millipore). The filtrate was diluted 1:5 and loaded onto a Dionex P100 analytical HPLC column, interfaced with Beckman System Gold HPLC system connected to a 32 Karat workstation. The chromatograms were analyzed with 32 Karat software (Beckman-Coulter).

Infection of Mice
Four- to five-week-old B6 or RNase L−/− mice were anesthetized with isoflurane (IsoFio, Abbott Laboratories) and inoculated intraperitoneally with A59 or ns2-H126R (200 PFU) in 50 µl PBS containing 0.75% BSA. At 3, 5, and 7 d.p.i., animals were sacrificed, livers, spleens, lungs, and kidneys were harvested, and viral titers in lysates were determined by plaque assay (Gombold et al., 1993). Alternatively, organs were used for RNA isolation or immunohistochemistry.

This study was carried out in strict accordance with the Guide for the Care and Use of Laboratory Animals and the Public Health Service Policy on Humane Care and Use of Laboratory Animals. The protocol was approved by the University of Pennsylvania’s Institutional Animal Care and Use Committee (permit number A3079-01).

Histology and Immunohistochemistry
Livers were fixed overnight in 4% paraformaldehyde, embedded in paraffin and sectioned. Sections were stained with hematoxylin and eosin or alternatively blocked with 10% normal donkey serum and immunostained with primary antibodies (1:1000 dilution of monoclonal antibody against Mvh nucleocapsid (N) protein or a 1:1000 dilution of polyclonal antibody against caspase-3 antibody. Staining was developed using avidin-biotin-immunoperoxidase (Vector Laboratories).

Statistical Analysis
An unpaired two-tailed t test was used to determine statistical significance. Data were analyzed with GraphPad Prism software (GraphPad Software).

SUPPLEMENTAL INFORMATION
Supplemental Information includes Supplemental Experimental Procedures, three figures, and one table and can be found with this article online at doi:10.1016/j.chom.2012.04.011.

ACKNOWLEDGMENTS
We thank Drs. Kristine Rose, Serge Fuchs, Katalin Kariko, Rahul Kohli, Carolina Lopez, and Beth Schachter for discussion and editing. We thank Dr. Stuart Siddell, University of Bristol, England, for inf-Mvh-A59 and inf-ns2-H126R and inf-ns2-H126R/ΔHdA, Dr. Reinhard Seddemeier, Ingenium Pharmaceuticals GmbH for the 2’-PDE cDNA clone, and Dr. Bryan R.G. Williams, Monash Institute, Melbourne, Australia, for the PKR−/− mice. A.E.G. acknowledges his prior collaboration with Dr. E. Snijder on the anti-2-5A activity of ns2. This work was supported by NIH grants R21-Al-080797, R56-Al-095285, and RO1-NS-054695 (S.R.W.) and RO1-CA044059 (R.H.S.). A.E.G. was supported in part by the Leiden University Fund. R.H.S. is a consultant and inventor on patents relating to RNase L licensed to Allos BioPharma.
